NATURE:

FIFTY-FIRST VOLUME.

L'ENVOI.

THE completion of a period of twenty-five years, and the publication of fifty volumes since NATURE was established, mark an epoch in its history. The :ditor is anxious to take advantage of it to tender his best thanks to those who have, 'om the commencement of the Journal to the present time, not only contributed to s pages, but have so freely permitted him to appeal to them for advice and assistance.

He feels strongly that it is only owing to their aid and their careful pilotage that ɴATURE has so far escaped that shipwreck which has been the lot of somewhat similar entures, not only in this country, but in Europe and America.

It would have been appropriate, if it had been possible, to have included in his, the first number of the fifty-first volume, a retrospect of the scientific progress .chieved during the last quarter of a century. It was, however, plainly impracticable n such a limited space to give a just idea of the various triumphs which have been ιccomplished along the many lines of scientific thought and work.

But no elaborate retrospect is needed to prove that since 1869 our scientific progress has been at a rate which has never been surpassed in the world's history. Men and ideas have increased ten-fold; instruments and applications have increased ι hundred-fold. The battle of scientific education has been fought and won, and the general interest in matters scientific is greatly increasing. Not only are these things so, but there is every indication that when L'ENVOI to the hundred and first volume comes to be written—by some other hand—a still more rapid progress will have to be indicated.

That the same distinguished man of science who wrote the first article in NATURE in 1869 has been good enough to start the fifty-first volume, will doubtless be as great a source of pleasure to the readers of NATURE as it is a source of pride to

THE EDITOR.

During the last twenty-five years the following have been among the Contributors to NATURE:—

Abbe, Prof. Cleveland (Washington).
Abel, Sir F. A., K.C.B., F.R.S.
Abercromby, Hon. Ralph.
Abney, Captain W. de W., C.B., F.R.S.
Acland, Right Hon. A. H. D., M.P.
Acland, Sir H. W. D., K.C.B., F.R.S.
Adami, Dr. J. G.
Adams, Prof. J. C., F.R.S.
Adams, Prof. W. G., F.R.S.
Adamson, Prof. R.
Agassiz, Prof. Alexander (Camb., Mass.).
Airy, Sir G. B., F.R.S.
Aitken, J., F.R.S.
d'Albe, E. E. Fournier.
Allen, Grant.
Allman, Prof. George James, F.R.S,
Allman, Prof. George Johnston, F.R.S.
Allardice, Prof. R. E.
Andrewes, Dr.
Archibald, E. D.
Argyll, Duke of, K.G., F.R.S.
Armstrong, Lord, F.R.S.
Armstrong, Prof. H. E., F.R.S.
Ayrton, Prof. W. E., F.R.S.
Baker, Sir Benjamin, F.R.S.
Baker, Sir Samuel W., F.R.S.
Baker, J. G., F.R.S.
Balfour, Prof. Francis, F.R.S.
Balfour, Henry.
Balfour, Prof. I. B., F.R.S.
Ball, John, F.R.S.
Ball, Sir R. S., F.R.S.
Ball, Dr. V., F.R.S.
Bamber, E. F.
Barlow, W. H., F.R.S.
Barrett, Prof. W. F., F.R.S.

Barus, Dr. Carl.
Bashforth, Rev. F.
Basset, A. B., F.R.S.
Bastian, Dr. H. C., F.R.S.
Bate, C. Spence, F.R.S.
Bates, H. W., F.R.S.
Bather, J. A.
Bauerman, Hilary.
Beale, Dr. Lionel S., F.R.S.
Beard, Dr. J.
Beddard, F. E., F.R.S.
Beddoe, Dr. J., F.R.S.
Bedford, Dr. J.
Bedson, Prof. Philips.
Beer, Dr. Berthold.
Bell, Sir I. Lowthian, F.R.S.
Bennett, A. W.
Bentham, George, F.R.S.
Berkeley, Rev. M. J., F.R.S.
Bettany, G. T.
Bevan, E. J.
Bickerton, Dr. T. H.
Bidwell, Shelford, F.R.S.
Black, William.
Blake, Prof. J. F.
Blanford, H. F., F.R.S.
Blanford, Dr. W. T., F.R.S.
Bloxam, G. W.
Blyth, Dr. E.
Bonney, Prof. T. G., F.R.S.
Bordage, Dr. E. (Paris).
Bottomley, Dr. J. T., F.R.S.
Boulenger, G. A.
Bourne, Dr. G. C.
Bowditch, Dr. H. P.
Bower, Prof. F. O., F.R.S.
Boyce, Prof. R.
Boys, Prof. C. V., F.R.S.
Braithwaite, Dr. R.
Bramwell, Lord, F.R.S.
Bramwell, Sir F. J., F.R.S.
Brandis, Sir D., K.C.I.E., F.R.S.
Brinton, Dr. D. G.
Britten, James.
Brock, Dr. H.
Brough, B. H.
Brown, H. T., F.R.S.
Brown, Prof. A. Crum, F.R.S.
Browne, Sir J. Crichton, F.R.S.
Bruce, Dr. J. Mitchell.
Brunton, Dr. T. Lauder, F.R.S.
Bryan, G. H.
Bryant, R.
Buchan, Dr. Alexander.
Buchanan, J. Y., F.R.S.
Budge, Dr.
Bulman, G. W.
Burnside, Prof., F.R.S.
Busk, George, F.R.S.
Butler, G. W.

Calderwood, W. L.
Capron, J. Rand.
Carpenter, Dr. P. H., F.R.S.
Carpenter, Dr. W. B., F.R.S.
Carruthers, W., F.R.S.
Carus-Wilson, C.
Carus-Wilson, Prof. (Montreal)
Cayley, Prof. A., F.R.S.
Champion, G. C.
Chaney, H. J.
Chisholm, H. W.
Christie, W H. M., F.R.S.
Chrystal, Prof.
Church, Prof. A. H., F.R.S.
Clarke, C. B., F.R.S.
Clerke, Miss A. M.
Clifford, Prof. W. K., F.R.S.
Clowes, Prof. W.
Cockerell, Prof. T. D. A.
Cockle, Sir J., F.R.S.
Collins, F. Howard.
Cole, Prof. G. A. J.
Colomb, Vice-Admiral.
Common, Dr. A. A., F.R.S.
Cooke, Dr. M. C.
Cope, Prof. E. D. (Phila.)
Copeland, Dr. Ralph.
Core, Prof. T. H.
Corfield, Prof.
Cornish, Vaughan.
Courtenay, W. L.
Creak, Captain, R.N., F.R.S.
Croll, Dr. J., F.R.S.
Crookes, W., F.R.S.
Cross, C. J.
Cunningham, J. T.
Cunningham, Lieut.-Colonel A.

D'Abbadie, A.
Dallinger, Rev. Dr., F.R.S.
Dana, Prof. J. D. (Newhaven, Conn.).
Darwin, Charles, F.R.S.
Darwin, Francis, F.R.S.
Darwin, Prof. G. H., F.R.S.
Davison, Charles.
Dawkins, Prof. W. Boyd, F.R.S.
Dawson Principal Sir J. W., F.R.S. (Montreal).
Day, Dr. F.
De Chaumont, Dr.
De Fonvielle, W. (Paris).
De La Rue, Warren, F.R.S.
Denning, W. F.
De Rance, C. E.
Dewar, Prof. J., F.R.S.
Dickins, F. V.
Distant, W. L.
Dittmar, Prof., F.R.S.
Dixon, Prof. H. B., F.R.S.
Dodgson, Rev. C. L.
Dohrn, Dr. A. (Naples).
Donnelly, General Sir J. K., C.B.
Douglass, Sir J. N., F.R.S.
Dreyer, Dr. J. L. E.
Du Bois-Reymond, Prof. (Berlin).
Duncan, Dr. P. M., F.R.S.
Dunell, J. R.
Dunkin, E., F.R.S.
Dunstan, Prof. W. R.
Dupré, Dr. A., F.R.S.
Dyer, W. T. Thiselton, C.M.G., F.R.S.

Ebbels, Arthur.
Edgeworth, Prof. F. Y.
Edwards, Prof. A. Mead (Boston, Mass.).

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

"To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

THURSDAY, NOVEMBER 1, 1894.

PAST AND PRESENT.

JUST five-and-twenty years ago, the Editor of NATURE did me the honour to request that I would write the leading article for his first number. In complying with my friend's wish, I said that I could think of no more appropriate preface to a journal, the aim of which was "to mirror that fashioning by nature of a picture of herself in the mind of man," which is called science, than an English version of the wonderful rhapsody *Die Natur*, which is to be found among Goethe's works,[1] and which had been a source of instruction and delight to me from my youth up.

Whether my estimate of the fitness of these pregnant aphorisms for the place assigned to them was shared by more than half-a-dozen of the readers to whom they were submitted, is very doubtful; indeed, I feel bound to confess that a rumour reached my ears, to the effect that some authorities, apparently of the school of the most noble Festus, in their haste, failing to discriminate between the great poet and his translator, opined that much attempt to learn, if not much learning, had made me mad.

A verdict based on a mistake so flattering to any literary vanity I might possess could be borne with equanimity. Indeed, in view of the general state of opinion among those interested in physical science at the time, I had no right to imagine that a presentation of a theory of the universe based exclusively upon the scientific study of nature—a prose poem, which stands in somewhat the same relation to the philosophy of Spinoza as the "Essay on Man" to that of Shaftesbury and Bolingbroke—would be intelligible to more than a small minority; or acceptable to more than a fraction of even that fit though few company.

At that time, it was rare for even the most deservedly eminent of the workers in science to look much beyond the limits of the specialty to which they were devoted; rarer still to meet with any one who had calmly and clearly thought out the consequences of the application, in all the regions into which the intellect can penetrate, of that scientific organon, the power and fruitfulness of which, within their particular departments, were so obvious. Though few read, and fewer still tried to comprehend the writings of Francis Bacon, a respectable, almost venerable, tradition bid us glorify him as the guide, philosopher, and friend of science; and more especially held him up as our exemplar in his insistence upon the division of the world of thought into two—an old and a new—but, unlike the corresponding divisions of the terrestrial surface, separated by impassable barriers. In the new, the strict adherence to scientific method was inculcated, and a rich reward of benefits to man's estate promised to the faithful; in the old, on the contrary, scientific method was to be anathematised, while absolute dependence was to be placed on quite other mental processes. Men were called upon to be citizens of two states, in which mutually unintelligible languages were spoken and mutually incompatible laws were enforced; and they were to be equally loyal to both.

People engaged in the ordinary business of life were not much troubled by difficulties which were not forced upon them by their avocations. Nor, among the men of science, did they press hardly on the mathematicians, the physicists, and the chemists.

[1] A better translation than mine and an interesting account of the very curious obscurity which hangs about the parentage of *Die Natur* are to be found in Mr. J. Bailey Saunders' recently published "Goethe's Aphorisms and Reflections."

At one time, the astronomers underwent sundry perturbations, yet these somehow got smoothed over and ignored. But there was serious trouble among the geologists and biologists. However sincerely they might try to shut their eyes, it was impossible to be wholly blind to the fact that for them the two worlds were not separable. On the contrary, it was becoming plainer and plainer that a vast tract, hitherto claimed for the old, was being steadily invaded and annexed by the citizens of the new world.

Fifty years ago the tension was already serious, but matters had not got so far as to seem desperate. It was possible for very eminent and, at the same time, perfectly sincere men, to keep their scientific and their other convictions in two separate logic-tight compartments. Indeed, it was said that some, perhaps too deeply bent on the search after final causes, found a reason for the duplicity of the cerebral hemispheres, in their adaptation to the purposes of this duplex intellection. Conducive to outward and inward peace as might be the convention, in virtue of which science was to be kept grinding at the mill of utility, and (by way of completing the resemblance to Samson) carefully blinded, or at any rate hoodwinked lest glimpses of a nobler field of action should end in an outbreak on the Philistines, the difficulty of observing it, as uniformitarian principles obtained the ascendant among the geologists, became insuperable. Outside the narrow circle of the peace-at-any-price "reconcilers," the *pax Baconiana* was plainly coming to an end in the middle of the century. It was finally abolished by the publication of the "Origin of Species."

The essence of this great work may be stated summarily thus: it affirms the mutability of species and the descent of living forms, separated by differences of more than varietal value, from one stock. That is to say, it propounds the doctrine of evolution as far as biology is concerned. So far, there is nothing new in Darwin's enterprise. So far, we have merely a re-statement of a doctrine which, in its most general form, is as old as scientific speculation. So far, we have the two theses which were declared to be scientifically absurd and theologically damnable by the Bishop of Oxford at the meeting of the British Association at Oxford in 1860.

It is also of these two fundamental doctrines that, at the meeting of the British Association in 1894, the Chancellor of the University of Oxford spoke as follows:—

"Another lasting and unquestioned effect has resulted from Darwin's work. He has, as a matter of fact, disposed of the doctrine of the immutability of species."

And

"Few now are found to doubt that animals separated by differences far exceeding those that distinguish what we know as species have yet descended from common ancestors."[1]

Undoubtedly, every one conversant with the state of biological science is aware that general opinion has long had good reason for making the *volte face* thus indicated. It is also mere justice to Darwin to say that this "lasting and unquestioned" revolution is, in a very real sense, his work. And yet it is also true that, if all the conceptions promulgated in the "Origin of Species" which are peculiarly Darwinian were swept away, the theory of the evolution of animals and plants would not be in the slightest degree shaken.

Ever since I began to think over these matters it has been clear to me that the question whether the forms of life on the globe have come about by evolution, or in some other way, is an historical problem, and must be treated as such. Either there are records of the process, or there are not. If there are not, we are shut up to the devising of more or less probable hypotheses based on indirect evidence. If there are adequate records, our business is to decipher them, and abide by what they tell us. Now, in 1859, there was no doubt about the existence of records; nor any about the fact that they extended over a vast period of time; nor any about the order of succession of the facts they registered. But, there was also no doubt in the mind of any one who looked critically into these records, that, in spite of their seeming copiousness, they were the merest fragments, torn and tattered remnants of the continuous series of documents which once existed. But, very largely in consequence of the stimulus given by Darwin, palæontological research was taken up with new vigour, and with marvellous success. So that, in 1878, I felt justified in writing—

"On the evidence of palæontology, the evolution of many existing forms of animal life from their predecessors is no longer an hypothesis but an historical fact."[2]

And in 1880—

"If the doctrine of evolution had not existed, palæontologists must have invented it, so irresistibly is it forced upon the mind by the study of the remains of the Tertiary Mammalia which have been brought to light since 1859."[3]

I am not aware that these statements have ever been controverted; and, in view of the following deliverances of the author of the most authoritative recent treatise on Palæontology, I think they are not likely to be:

[1] British Association for the Advancement of Science, Oxford, 1894. Address of the Most Hon. the Marquis of Salisbury, President.
[2] "Collected Essays," vol. ii. p. 226. [3] *Ibid.*, p. 241.

"Recent investigations have utterly shattered the belief in cataclysms. The conviction has arisen that the process of the development and metamorphosis of organic beings was gradual and uninterrupted, and that sharp lines of demarcation are to be found only where considerable changes in the conditions of existence, and especially in the distribution of land and water, have brought about great modifications in the world of life or interruptions in the formation of sediment." (Zittel: 'Handbuch der Palæontologie." Bd. I. p. 23.)

And, again, in the recently completed final volume of this standard work we read:

"The whole history of the evolution of the mammalia from the Trias to the present day, in spite of all deficiencies in the record, plainly shows that the genetic connection of the several Faunæ, whatever geological disturbances may have taken place, was never completely interrupted; and that each of these associations of animals has arisen by gradual transformation of the constituents of its predecessor, and has furnished the stock of its successor." (Bd. IV. p. 764.)

However often, therefore, thoughtlessness, or polemical dexterity, may confuse issues which are totally distinct, biological evolution rests, in perfect security, on the firm foundation afforded by the study of the remains of the animals and plants, which have successively peopled the world during the untold ages of its past history. The coming into being of the present forms of life has happened so, and in no other way.

And, as I pointed out, sixteen years ago,

"It is only the nature of the physiological factors to which that evolution is due which is still open to discussion."[1]

For me, the claim of the doctrine of evolution to be taken into account in all philosophical and other views of the nature of things turns upon whether it possesses a solid foundation in fact or is a mere speculation. No doubt, whenever astronomers universally accept what is called the Kant-Laplace theory of the heavens, a notable addition will be made to this indispensable objective foundation of the doctrine. Whenever chemists accept the evolution of the so-called elements from a *materia prima*, there will be a further grand addition. But, for the present, I venture to suppose that the palæontological base is surest. And, at any rate, so far as the claims of science to be heard in regard to the problems of human life are concerned, it is, far and away, the most important. If man has come into existence by the same process of evolution as other animals; if his history, hitherto, is that of a gradual progress to a higher thought and a larger power over things; if that history is essentially natural; the frontiers of the new world, within which scientific method is supreme, will receive such a remarkable extension as to leave little but cloudland for its rival.

[1] "Collected Essays," vol. ii. p. 226.

Experience teaches me it is by no means impossible that if I were to stop here, what I have said would be represented, and even believed, to be a repudiation of "Darwinism." Yet no conclusion could be more utterly devoid of foundation.

"The combined investigations of another twenty years may, perhaps, enable naturalists to say whether the modifying causes and the selective power, which Mr. Darwin has satisfactorily shown to exist in nature, are competent to produce all the effects he ascribed to them; or whether, on the other hand, he has been led to over-estimate the value of the principle of natural selection, as greatly as Lamarck over-estimated his *vera causa* of modification by exercise."

.... "'My sons dig in the vineyard,' were the last words of the old man in the fable; and though the sons found no treasure they made their fortune by the grapes."

These two paragraphs occur at the end of the critical notice of the "Origin of Species," which I wrote in 1859. The citations I have already given from Zittel sufficiently show what has come of "digging in the vineyard"; there is another (Bd. I. p. 42) much to the present purpose.

"For the naturalist, evolution (*die Descendenz theorie*) offers the only natural solution of the problem of the development and succession of organic beings. But as to the causes which bring about the modification of species, and especially the change in a given direction, opinions are yet greatly divided. That the principle of natural selection, discovered by Darwin, leaves many phenomena unexplained is no longer denied by even the warmest followers of Darwin."

It will be observed that at any rate one of these "warmest followers" has never thought of denying it. On the contrary, he has over and over again brought the difficulties prominently forward. Nevertheless, I doubt as little, now as heretofore, that the probabilities are greatly in favour of our finding a way to the causes of evolution by pertinacious study of variation and natural selection. There are large fields for inquiry open on all sides. How much has yet been done, for example, towards ascertaining the effect of external conditions on the struggle for existence within the organism and the production of varieties as a consequence of that struggle; or towards an adequate experimental study of variation? The supposition that problems such as these, and others that might easily be mentioned, could be finally solved, even in thirty-five years, is one that would not enter the mind of a competent biologist; and the parade of the mutual contradictions and the intrinsic weaknesses of the hypotheses which, hitherto, have been more or less tentatively propounded, as if they had anything to do with the truth or falsehood of the doctrine of evolution, should not be taken too seriously.

T. H. HUXLEY.

ECONOMIC PRODUCTS OF INDIA.

A Dictionary of the Economic Products of India. By George Watt, M.B., C.M., C.I.E., assisted by numerous contributors. In six volumes (vol. vi. in four parts), 1889-1893. Published under the authority of the Government of India, Department of Revenue and Agriculture. (Calcutta: Superintendent of Government Printing.)

THE completion of this important work adds enormously to the facilities previously existing for acquiring a knowledge of the vegetable, mineral, and animal products of our Indian empire. The object of the dictionary is to give a complete account of all Indian products that have been in any way utilised by man, however small or trivial the use of them may have been. As a large majority of the products are of vegetable origin, the appointment of a botanist as editor and principal author was essential, and the Government of India may be fairly congratulated on the result.

In the preface to the first volume the author states that he has had "to keep in view a two-fold purpose; viz. on the one hand to supply scientific information which may be useful to the administrative officer, and on the other to meet the requirements of the reader in search of definite information regarding Indian economics." Whether another purpose was to produce a large book is not stated, but no feature of the work is more conspicuous than that it consists of nine bulky and rather closely-printed volumes.

In general plan the dictionary consists of long and elaborate accounts of the more important articles of commerce produced in India, such as various grains, dyes, oils, tea, cotton, sugar, indigo, wool, silk, &c., and shorter notices of less valuable products. As a general rule each vegetable product is described under the scientific name of the plant from which it is obtained, cross references being supplied where necessary under English and Indian terms, and also under general headings, such as "Oils and Fats," "Timbers," &c. Animal and mineral products are described under various headings. A general index is promised, and is needed, for many important English and vernacular terms are not found in their places. For instance, silk-cotton, semul, jowári and juári, bájra, cholum, cumboo, charas, ganja, ngápi, civet (and Viverra) may be searched for in vain. Tasar is inserted, but there is no reference to tusser or tussah, the common spelling, in the place where these words would come in alphabetical sequence. The article on isinglass is slightly out of its proper place, and that on sharks' fins and fish maws, to which reference is made under both isinglass and fish, appears to have been omitted.

Each article, in the case of vegetable products, consists of the scientific name of the plant, with references, the English name, if one exists, and a list of vernacular names, followed by full references to the works, scientific or economic, in which the plant or its products have been described. Then follow paragraphs on the habitat, history and useful products, such as dyes, fibres, oils, gums, &c., each under a separate heading. Sometimes a paragraph explains the chemical composition. Under additional headings are related the uses to which the plant or its products are put in medicine, food, or the arts, and to the paragraph on medicine another is frequently added with "special opinions" by various medical officers. In the case of trees the structure of the wood receives special notice. The last paragraph of each article describes the "domestic and sacred uses." With mineral and animal products the plan is similar, but details are given, as a rule, under general headings, such as horns, skins, wool, iron, &c. In the first volume a botanical diagnosis of each plant is generally added, but not in the later volumes. A number for each separate product or use is inserted in the margin to facilitate reference, the numbers commencing afresh under each letter of the alphabet.

The longer articles contain full descriptions of cultivation, trade, manufactures, and other important subjects.

Whilst the bulk of the work is by Mr. Watt, many articles have been contributed, partly or wholly, by other writers. The list of contributors affixed to the first volume refers only to that volume, or to that and the second, for in the prefaces to the third and subsequent volumes several additional names are mentioned, one of them, Dr. J. Murray, being that of the author of several important articles. All of the principal contributors, except Mr. Watt (and he holds the degree of M.B.), belong to the Indian Medical Service, so that it is not surprising to find a very large space devoted to drugs and therapeutics. In fact, the whole work might fairly be termed a dictionary of economic products and materia medica. Many of the plants catalogued are apparently included solely because of some medicinal or supposed medicinal use, frequently by ignorant people. For example, on the last two pages of the work, *Zornia diphylla* is introduced on account of its use thus quoted under the head of "Medicine": "The root is given, along with that of *Bhadar jhapni*, to induce sleep in children. These plants shutting up their leaves at night have probably suggested the idea to the Ojhas." The quotation is from a report by Mr. Campbell on the "Economic Products of Chutia Nagpur." No reference can be found to *Bhadar jhapni* in its place in the dictionary.

The "special opinions," quoted from various medical writers on therapeutics, are of a miscellaneous nature, and no distinction is drawn between notices of the purposes for which drugs are used by competent physicians, and those of occasions on which they are prescribed by ignorant hakims or superstitious herbalists. All this part of the work might have been omitted with advantage; however useful such opinions might be in a special work on drugs and therapeutics, the details are out of place in a description of economic products. One instance may be quoted. Under the head of "Diamond," the following occurs: "*Medicine.*—Diamond dust is known to be a powerful mechanical poison. In Hindu practice it is, however, to some extent used as a drug" (just as gold, silver, pearls, and other precious substances are regarded by unscientific races as possessing great medicinal virtues). The whole extract is too long to quote, but the "special opinion" runs thus: "Employed as a poison, it is administered in the shape of dust, as in the late celebrated case when the Resident of Baroda, Sir Arthur Phayre, nearly lost his life." The Resident of

Baroda was Sir Robert Phayre, not Sir Arthur, the well-known Chief Commissioner of Burma, and the risk to life was due to an important fact which the distinguished surgeon, whose name is appended to the quotation, must have forgotten, the admixture of arsenic with the diamond dust. The latter is simply a mechanical irritant like quartz sand, or powdered glass, and to term any of these a powerful mechanical poison is to use a stronger term than is quite accurate.

The devotion of a large space to therapeutics is not the only instance in which the bulk of the work is increased by the discussion at length of matters that have but slight connection with the main subjects of the dictionary, as specified by the author. Perhaps the utilisation of several pages under *Triticum sativum* (wheat) in the discussion of the depreciation of silver, may be thought essential, but it is not clear why, under *Papaver somniferum*, long extracts should be quoted from various dispatches to illustrate the attitude of the Government of India on the Chinese opium question, nor what bearing on the economic products of India the seven pages can have, under *Vitis vinifera*, that are taken up with the history of the vine and of wine. Amongst the longer articles, 63 pages are given to tea (in addition to 19 on *Camellia theifera*), 77 to tobacco, 87 to indigo, 88 to opium, 123 to sheep, goats, wool and woollen manufactures, 152 to rice, 174 to cotton, 238 to silk and silk manufactures, and 380 to the sugar-cane and sugar. Almost every one of these articles would require a separate notice for adequate discussion. For many purposes a condensed account of the history, production, manufacture, and trade in each case would be more generally useful as well as more interesting; but, on the other hand, it is extremely difficult for the author of a work like the present to select only those data that are useful, and no editor can be expected to possess the special knowledge of every separate subject that will enable him to do justice to it, and to avoid mistakes.

In the preface to the first volume it is stated that economic products which belong to the animal and mineral kingdoms have been but very imperfectly touched upon. This plan, however, appears to have been modified subsequently, since silk and wool, as already noticed, form the subjects of two of the longest articles. The accounts of minerals have, for the most part, been written by officers of the Geological Survey, or copied from the Survey publications. It is questionable, however, if any geologist can have written the following passage under the heading of iron: "*Clay ironstone* exists in large deposits in many coal-measures, and in this situation is known as *black band*." It is, of course, only one variety that is known by this name.

No parts of the dictionary, however, stand more in need of scientific revision than those relating to vertebrate animals. A few instances will show this. A short article on "Pheasants, Jungle-fowl, Partridges, &c.," commences thus: "The pheasant families of birds, *Phasianidæ*, *Megapodidæ*, and *Gallinæ* (*sic*) comprise the pea-fowl, pheasant, jungle-fowl, and spur-fowl, while the partridge family, *Tetraonidæ*, includes the partridge, snow-cock, and certain forms of quail." A list follows in which the genera *Pavo*, *Argusianus*, and *Polyplectron* only are included in the family *Phasianidæ*, all other pheasants, amongst them the typical genus *Phasianus*, are placed with *Megapodius nicobariensis* in the family *Megapodidæ*, and the so-called family *Gallinæ* (which is really a sub-family of *Phasianidæ*) contains *Gallus* and *Galloperdix*. These mistakes are apparently copied from Murray's "Avifauna of British India." In the article "Oxen," the wild and tame yaks are rightly classed as one species, but the tame buffalo is separated, under the name of *Bubalus bos*, from the wild race, or *B. arni*. No reason is assigned for a distinction that is quite opposed to the views of all modern writers on mammalia, nor is any authority given for the name adopted, which is simply the old Linnæan name *Bos bubalus* reversed.

The omission of any notice of ngápi in its proper place has already been mentioned. This curious compound of partially decomposed fish with salt is a most important article of food in Burma, where it may be said to replace butter and cheese amongst a people, who, like the Chinese, hold milk and all substances obtained from it in abhorrence. The manufacture of ngápi is on a very large scale, and the trade in the article is extensive, yet apparently the only notice of the mode of preparation that occurs in the dictionary ("Fish," vol. iii. p. 367) is apparently erroneous, and certainly does not apply to one of the ordinary processes. Three or four different kinds of ngápi are mentioned in the *Burma Gazetteer*, and their manufacture described; all the processes are radically distinct from that briefly quoted in the dictionary, whilst no information is given in the latter as to the trade in the article or its value, except what may be inferred from the fact that the revenue from Burmese Fisheries in 1883 was twelve to thirteen lakhs of rupees.

In the article on sheep and goats, and in some others, the authorities for scientific names are quoted on the botanical, not on the zoological system, and it is rather strange to find the nilgai called *Boselaphus tragocamelus*, W. Sclater (instead of Pallas), and the Tibetan gazelle, *Gazella picticaudata*, Brooke (instead of Hodgson). The mutton of the dumba, or fat-tailed sheep, is said to be very coarse, whereas it is the best mutton in Asia. The common Indian story, repeated in the dictionary, under "Camel's milk," that the sweetmeat halwa, brought from the Persian Gulf, is composed of camel's milk and honey (vol. ii. p. 64), is a mistake. Errors like the two last (others might be quoted) are liable to occur in a work like the present, but the number of mistakes of various kinds in the articles on animals and animal products appears to be rather large. It is not easy to understand why, in an important Government work like the present, the aid of competent zoologists could not be obtained to revise the proofs.

A serious mistake may be pointed out in an article on the yeast plant, described under the somewhat pedantic heading of *Cerevisiæ fermentum*. Yeast, it is said, "lives and increases in the fermenting liquor, but appears to abstract nothing from it." This mistake may however have been noticed, for in a later article, on "Malt liquors," a correct account of the growth and nutrition of yeast is quoted.

One presumably Indian economic product, paper, can scarcely be said to be favourably represented by the material used in the present work, nor are the type and printing, especially in the later volumes, the best ever produced in India. Misprints are numerous. One is amusing: the Tibetan antelope is credited with no less than ten horns. It is to be hoped that commentators on the Apocalypse will not be led to believe that a ten-horned beast really inhabits Tibet.

On the whole, whilst in case a second edition is required, careful revision is desirable, which might in some cases take the form of abridgement and the omission of irrelevant matter, the principal feature of the work is the large amount of energy that has been expended in its preparation, and the great effort that has been made to bring together information from all quarters. To write a complete account of the products of India, and to give a full scientific and economic description, both of the products themselves and of the sources from which they are derived, are tasks far beyond the powers of any single individual, and that could only be thoroughly carried out by a committee of specialists. W. T. B.

CHINESE AND JAPANESE BUTTERFLIES.

Butterflies from China, Japan, and Corea. By John Henry Leech, B.A., F.L.S., F.Z.S., F.E.S., &c. 4to. With forty-three coloured plates. (London: R. H. Porter, 1892–1894.)

UNTIL within the last few years, almost nothing was known of the Palæarctic fauna, except that of Europe and the Mediterranean sub-region, and though butterflies are the most attractive and the easiest collected of all insects, those with which we were acquainted from Siberia, the greater part of China, and Japan, might almost have been counted on the fingers.

Since then, however, great progress has been made. In the first place, Russian exploration and consolidation have opened up vast regions of previously almost unknown parts of Asia to science, and the work begun on the Amur and in Turkestan by Schrenck and Fedchenko, has been worthily continued by the Grand Duke Nicholas Mikhailovitch and his coadjutors, among whom the brothers Groum-Grshimaïlo deserve the place of honour. When shall we see one of our own Royal Princes bringing out a work on the insects of one of our own colonies to compare with Romanoff's "Mémoires sur les Lépidoptères?" In Western Europe, such work is left to private enterprise.

The French Jesuit missionaries, especially the Abbé David, have penetrated to such out-of-the-way parts of China, as Mou-pin, and have brought back large collections of different kinds, including many very remarkable butterflies, which have been illustrated by Oberthür in his "Études d'Entomologie."

Since the time when China and Japan were thrown open to Europeans, English entomologists have not been behindhand in the work of collection and description. The fine collections formed in Japan by Lewis, Pryer, and Maries have been worked out so well by Dr. Butler and others, that the Lepidopteræ of Japan are now more thoroughly known than those of any other part of Asia except British India. The late Mr. W. B. Pryer published a work on the butterflies of Japan, in the country itself, in English and Japanese, with coloured plates of all the species known to him; but as this book is scarce, and the letterpress very meagre, we are glad that Mr. Leech has included Japan in the important work which forms the subject of the present article.

Mr. Leech commenced his entomological career by the publication of a useful little volume on British *Pyralidæ*, and by collecting excursions to the Canary Islands, Brazil, &c. Subsequently he became interested in the fauna of Eastern Asia, and devoted eight years to its study, and to the accumulation of materials for the present work, not only by employing experienced collectors like Pratt and Kricheldorf to explore the interior of China, but by personally visiting and forming large collections in the Himalayas, Corea, and Japan; in Japan, indeed, he succeeded in capturing almost every species of butterfly known to inhabit the country. By this means, he gradually accumulated the fine collections on which he has based his great work, in which he has been able fully to describe 650 species, a large proportion of which are figured in the forty-three excellent coloured plates which accompany it. We have also a map, and five plates of scenery (four of Western China and one of Japan), the second of which exhibits a side-view of the tremendous and almost perpendicular face of the mountain of Omei-Shan, in the neighbourhood of which Mr. Pratt obtained many of the most beautiful and interesting butterflies which he discovered.

The usefulness of the work is increased by an interesting introduction, dealing with the literature of the subject, the countries visited by the author and his collectors, and a table of geographical distribution, divided into the following columns: Japan, China, Corea, Amurland, Himalayas, Thibet, Europe, and "other countries and regions."

The author remarks in his preface: "It is a matter of regret that, owing to an almost complete absence of information respecting habits and life-histories of the majority of the species, the work is unfortunately less complete than the author could have wished." All honour to him for saying so. It is the duty of every entomologist to seek for and record everything of the kind which he can obtain; but entomologists are sometimes too much disposed to care only for the specimens they receive, and it would not occur to them to encourage their collectors, as they easily might do, to record anything more than dates and localities. Mr. Leech, however, seems both to have sought for and utilised such information, so far as it was accessible or obtainable.

On examining Mr. Leech's 650 species of butterflies, which are distributed among rather more than 150 genera, it becomes apparent that they are to a large extent mainly an amplification of the European fauna. About 300 species are found in Europe proper, divided into about 50 genera, of which only about 9 genera, each including but one, or at most two or three, species of very limited range, are not represented in Mr. Leech's work. These are *Triphysa*, *Nemeobius*, *Aurotis*, *Thestor*, *Zegris*, *Doritis*, *Spilothyrus*, *Thymelicus*, and *Cyclopides*; and there is no reason why some, even of these, should not extend to Western China. In China the European and Indian faunas meet and mingle; thus in the *Satyrinæ*, the Mountain Brown butterflies of the genus

Erebia are far more sparingly represented in China than in Europe; but *Lethe* is far better represented in China than in India, and *Ypthima* at least as well. The tropical subfamilies *Morphinæ* and *Acræinæ* are also represented in China, the first by four species, one of which, *Stichophthalma howqua*, is as large and handsome as a South American *Morpho*, and the other by one of the two Indian species, *Pareba vesta*, which extends its range to several parts of South-Western China. In Japan and the extreme east of China, we find one or two species belonging to peculiarly Nearctic forms, such as *Anthocharis scolymus*, for example.

In certain large genera, such as *Zephyrus*, *Thecla*, and *Papilio*, the number of Chinese species far exceeds those known to occur in Europe; but in the case of *Papilio*, at least, this is mainly due to the large number of properly Indian species which extend their range to China.

It is among the *Papilionidæ* and *Pieridæ* that we find some of the most interesting of the Chinese and Central Asian forms, especially those allied to *Parnassius*, *Aporia*, and *Colias*. There are only about thirteen well-marked genera of *Papilionidæ*, except the heterogeneous genus *Papilio* itself; and eight of these are represented in Mr. Leech's district, the other five being *Hypermnestra* (South-West Asia), *Eurycus* (Australia), *Euryades* (South America), *Thais* (South Europe), and *Bhutanitis* (Bootan). The headquarters of *Parnassius*, however, are perhaps in the mountainous districts rather beyond the range of the present work, as Mr. Leech enumerates only eight species, which seems to us to be rather a small number. Many curious genera allied to *Aporia* are also found in the south-western districts of China bordering on Thibet, such as *Mesapia*, *Davidina*, &c., most of which bear a general resemblance to our Green-veined White (*Pieris napi*). Of these, Oberthür's genus *Davidina* is the most curious, as the wing-cells are divided by longitudinal nervures, a characteristic which we do not meet with in any other butterfly. Only four species of *Colias* are enumerated, the headquarters of this genus also being apparently rather beyond Mr. Leech's limits. He has, however, sunk all the Japanese forms described as distinct by various authors, as varieties of *C. hyale*, Fabr.; but this is one of those questions which will never be disposed of to the satisfaction of entomologists without long and careful breeding of the supposed varieties or species. Some authors, however, have certainly gone too far in regarding mere varieties of butterflies as entitled to specific rank; while others have erred more seriously in the opposite direction, by placing together perfectly distinct species as varieties. It frequently happens that species which subsequently prove to possess very important distinctive characters, have a much greater superficial resemblance to others than obtains between seasonal or otherwise dimorphic forms of insects which belong indubitably to the same species. But if a good species is sunk as a synonym or a variety, the next entomologist who considers it to be distinct will very likely overlook the previous notices, and describe it as new. We are constantly discovering that names which stand as synonyms in our books really belong to insects which have since been described as new under other names.

In taking leave of this extremely interesting book, we must congratulate Mr. Leech on having successfully brought to a conclusion a work which will hold a worthy place among the many valuable local butterfly faunas which have been published in England, of recent years, by Godman and Salvin, Moore, Trimen, Distant, and others.

OUR BOOK SHELF.

Rainmaking and Sunshine. By John Collinson. (London: Swan Sonnenschein and Co., 1894.)

THE only object there can possibly be in giving a notice of this book is to warn intending purchasers of its contents, lest they be deceived by the title, and hope to find some account, more or less interesting, of the experiments that were made in America, a short time back, with the view of procuring a rainfall. This book has not even that recommendation. One has not much patience with weather prophets, who base their assertions on conjunctions of the planets, or some equally occult and absurd methods; but Mr. Collinson is in advance of all such vendors of nostrums. Not for him the uncertain, or partial, fulfilment of hazily expressed prophecies, not for him the long and careful study of signs and portents; he, himself, is the rainmaker, he is the dispenser of sunshine and cloud, he is gifted with the divine power that storms and floods and drought obey. Here is his own modest statement: "Thus when suitably placed as to residence, the results of his (the author's) action on magnets are certain to produce changes in the weather, and other effects, as interesting and useful, bearing on meteorological science generally. They are simply marvellous. Storms, floods, drought, &c., can be induced, on the one hand, and the prevalence of sunshine and warmth, in opposition to coldness and gloom, on the other. His action in this direction, judging from experience, could bring any district, and, indeed, the country generally, such favourable weather as would recall the glories of the Golden Age." (p. 18.) Another passage that makes one doubt whether the book is to be taken seriously, relates how a prophet (Query Dr. Falbe, says the author) foretold bad weather for March 28, 1893, sudden fall of the barometer, great conflicts of wind and water, and various other disasters. "About the same time Prof. Jenkins foretold that there would be a cyclone with snow on March 25. I took care that these storms did not happen." (p. 186.)

But there is one form of internal evidence which forbids us concluding that the author has perpetrated an elaborate joke. He claims to have given to a whole nation of holiday-makers ten days of enjoyable weather at Easter, but refused to exercise his godlike gift on behalf of suffering humanity at the following Whitsuntide, because "NO" (in very large capitals) "suitable sign of appreciation had then been received from any of those who largely benefited by the results of the fine Easter weather." (p. 214.) One would like to know what is the force of "then" in this sentence. Have the railway companies rewarded this gentleman since? And what would be a suitable sign of appreciation to a man so endowed? But enough of this nonsense; whoever else the book may amuse or edify, it will scarcely find readers among the subscribers to NATURE.

The Elements of Graphic Statics: a Text-Book for Students of Engineering. By L. M. Hoskins, Professor of Pure and Applied Mechanics in the Leland Stanford Junior University; formerly Professor of Mechanics in the University of Wisconsin. (London: Macmillan and Co., 1892.)

ALTHOUGH the fundamental ideas of Graphical Methods in Statics can be traced back to the writings of Stevinus, of Bruges (*c.* 1600), and although they must have been employed by scientific engineers, such as Brunel, the subject of Graphical Statics as known to the mathematician dates only from Maxwell's writings on the subject, and to Culmann's elaborate treatise in German; also to Colonel Sir George Clarke's exhaustive work.

The subject of Statics, which had come to a standstill, was revivified by the graphical methods now employed by every engineer and architect.

But as the subject is nothing unless employed practically by the draughtsman on the drawing board, it has not yet conquered the prejudices of the abstract mathematician, although many problems of allied descriptive geometry, required in the construction of inertia ellipses and curves (Part iii.), are well worthy of the attention of the pure geometer.

The present treatise is designed as an elementary textbook for the use of students of engineering; and the illustrations are drawn carefully to scale, representing each some real object.

The method of lettering, attributed to Bow, is now more appropriately assigned to Henrici; the author very rightly insists upon the fundamental importance of this lettering, in emphasising the reciprocity existing in the diagrams.

Incidentally the method of Graphical Statics emphasises the proper treatment of Statical problems, which is always to consider a system of balancing forces; and thus to banish the word Resultant from Statics unless employed to represent the force which if reversed will balance the remaining forces of the system. G.

A Naturalist on the Prowl. By Eha. Pp. 257. (London: W. Thacker and Co., 1894.)

From Spring to Fall. By "A Son of the Marshes." Edited by J. A. Owen. Pp. 239. (London: William Blackwood and Sons, 1894.)

THE author of "A Naturalist on the Prowl" knows how to write pleasantly on the natural history of the Indian jungle. There is not a dull page in his book. It is only rarely that we meet with a volume so full of interesting observations, and so free from stodginess. In "Eha's" company we travelled from the first to the last page, here admiring the keenness of his perception, there laughing at his humorous comments, and always made happy by his geniality. He does not "prowl" to kill, neither is he imbued with the spirit that induces many people to collect shells and postage-stamps as specimens; for though he recognises that "without a collection, a man's knowledge of natural history becomes nebulous, and his pursuit of it dilettante," he also knows that there is a possibility of a man degenerating into a mere collector, and ceasing to be a naturalist. Mr. R. A. Sterndale enriches the volume with eighty illustrations, mostly sketched from life.

The works of "A Son of the Marshes," on country life and scenery, are renowned for their simple beauty and sympathetic expression. Under the editorship of Mrs. Owen, the volume before us, like other books by the same author, is delightful reading.

Edible and Poisonous Mushrooms. By Dr. M. C. Cooke. (London: S.P.C.K., 1894.)

IT may be safely asserted that fewer kinds of fungi are used for food in Great Britain than in any other country in Europe. This is the more remarkable when we take into consideration the indebtedness of the present advanced state of Mycology to the researches of our countrymen, amongst whom may be mentioned Bolton, Sowerby, Badham, Berkeley, and Broome. The author of the work under consideration has also contributed very materially to a knowledge of edible kinds of fungi by various publications, and more especially in promoting annual fungus forays in various parts of the country. Poisonous fungi liable to be confounded with the numerous edible kinds are very few in number, and the majority of casualties, both at home and abroad, are caused by eating *Amanita phalloides*, a fungus very different in appearance from the common mushroom (*Agaricus campestris*), but which, probably from its neat and attractive appearance and size, appears to commend itself to unsuspecting persons, and being usually very abundant and widely distributed, is likely to be a continual source of danger until its characters and general appearance are more generally known.

Dr. Cooke very properly condemns the various rule-of-thumb methods for discriminating between edible and poisonous kinds of fungi, and shows that the essential characters of the various kinds must be thoroughly grasped, as being the only certain means of identification; and this method, with Dr. Cooke's book as a guide, should not prove a difficult task. The written descriptions of the various kinds, without being technical, are very clear and to the point, and the eighteen coloured plates are excellent. Finally, the best methods of cooking are given. The book is well printed, attractive externally, and very cheap.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

What are Acquired Characters?

FOR some while past, as we all know, a great contest has been raging as to whether acquired characters of an organism can or cannot be transmitted from one generation to another; and mighty authorities, on the one side, say that they can be; and great authorities, on the other, aver that they cannot be.

As a spectator of this contest, I have tried to understand it; and, in the first place, I have endeavoured to make out what is meant by the phrase "acquired characters"; or, in short, what is meant by the word "acquired," as used, in this connection, by Weismann, his friends, and his antagonists.

It is evident that the word is not used in its primary and natural signification: for, as on the theory of evolution (on which hypothesis the whole discussion proceeds), man has been evolved from an amœba or an ascidian, or some other early form, it follows that every character by which a man differs from this, his first progenitor has been acquired at some time between the two termini of the course of evolution, and, if the word were used in its ordinary sense, it would further follow that none of these characters could be transmitted by man to his offspring. This is manifestly untrue, for the issue of a woman is not simply an amœba. In fact, Weismann himself implies plainly that he does not use the word "acquired" in its ordinary signification, and asserts that its scientific value lies in its restricted use. ("Essays on Heredity," English translation, vol. i., first edition, p. 412.)

It becomes then very important to get at an accurate and workable definition of the word "acquired" for the purpose in hand; and such a definition must, I conceive, satisfy the following conditions:—(1) It must be such as to include all characters that are "acquired" within the restricted meaning of the word, and to exclude all characters that are not within the meaning; (2) it must be stated in physical, and not in metaphysical terms; (3) it must not be stated in terms derived from hereditability or the contrary, or in terms of any hypothesis or theory; (4) in order that it may be of use for scientific purposes, it must be stated in terms that admit of ascertainment and verification.

Of the importance of a clear definition of these words every one must, I think, be conscious; and if authority were required, we have that of Prof. Weismann himself. "I should wish to point out," he says, "that we ought above all to be clear as to what we really mean by the expression 'acquired character.'" ("Essays," vol. i. p. 169.)

Now, I do not profess to have read all that has come from the pen of Prof. Weismann, and still less the whole literature that has gathered round the controversy; but, after some search, I have hitherto failed to find any definition which has satisfied me; and, furthermore, I do not feel quite sure that all the advocates and opponents of Weismann use the phrase in one and the same meaning; and my object in writing this, is to ask for some assistance in finding the real and true definition of the phrase as used by both sides in this controversy.

Let me, to assist in the discussion, refer to some of the hints for a definition which I have been able to find.

At pp. 98–99 of vol. i. of the "Essays upon Heredity" (English translation, first edition), Prof. Weismann, having referred to "modifications which appear as the direct consequence of some alteration in the surroundings," and to the effect of a strange climate, says: "It is difficult to say whether the changed climate may not have first changed the germ, and if this were the case, the accumulation of effects through the action of heredity would present no difficulty. For instance, it is well known that increased nourishment not only causes a plant to grow more luxuriantly, but it alters the plant in some distinct way, and it would be wonderful indeed if the seeds were not also larger and better furnished with nutritive material. If the increased nourishment be repeated in the next generation, a still further increase in the size of the seed, in the luxuriance of the plant, and in all other changes which ensue, is at any rate conceivable, if it is not a necessity. But this would not be an instance of the transmission of acquired characters, but only the consequence of the direct influence upon the germ cells, and of better nourishment during growth."

This passage hints plainly at a definition of acquired characters to this effect. An acquired character is one produced by an external stimulus acting on the organism but not influencing the germ cells, whilst every character produced by an external stimulus acting on the organism and influencing the germ cells would not be acquired. But how are we to ascertain whether the germ cells—not, be it observed, the embryo, but the germ cells—have been influenced? Is there any chemical or microscopic means of answering this question? Is this influence a physical fact capable of ascertainment, and if so, how? It seems almost as if the presence or absence of an influence on the germ cells respectively, were inferred from the capacity or incapacity of transmission. But if so, I can hardly suppose that any one would suggest that any light can be got from such a definition, for this would be to proceed in a circle, and to reduce the statement that acquired characters cannot be transmitted to the following identical and useless proposition, viz. characters which by experiment are found not to be transmitted, and are therefore said not to affect the germ cells, are not capable of transmission, *i.e.* characters incapable of transmission are incapable of transmission.

At page 170 of the same volume occurs a passage which seems to suggest a slightly different definition of acquired characters. "I am also compelled to admit," says our author, "that it is conceivable that organisms may exert a modifying influence on their germ cells, and even that such a process is, to a certain extent, inevitable. The nutrition and growth of the individual must exercise some influence upon its germ cells." But a little afterwards, p. 171, there occurs another passage which, if I understand it aright, throws doubt on this conclusion; but this I will for the present neglect. In other passages, *e.g.* at p. 406, our author refers to direct influence of an external stimulus, such as climate, intending, I conceive, to draw the distinction between direct and indirect influence of an external stimulus on the germ plasma. These passages appear to me to suggest the following propositions with reference to acquired characters, viz.: (1) Every change produced by an influence of the organism on its own germ cells is not an acquired character; (2) an external stimulus may act on the organism, and the organism on the germ cells, and so produce a non-acquired character; (3) every other change produced in an organism by an external stimulus is an acquired character.

But, assuming these propositions to be true, do they admit of ascertainment by any appeal to physical facts? Do we know by any examination—physical, chemical, or experimental—what influence an organism produces on its own germ cells? If we do, then these propositions may be useful, and acquired characters will be a category of changes capable of scientific establishment by the appropriate means of inquiry; but if not, then ey seem useless, except for the purpose of propounding an othesis or theory.

p. 169 of the same volume of "Essays upon Heredity," I find Prof. Weismann saying: "An organism cannot acquire anything, unless it already possesses the predisposition to acquire it: acquired characters are therefore no more than local or sometimes general variations which arise under the stimulus provided by certain external influences"; and then he proceeds to illustrate this by saying that the so-called "exercierknochen" or bony growth caused by the pressure of a weapon in drilling depends on the capacity of the bone to react on the stimulus. "Every acquired character is simply the reaction of the organism upon a certain stimulus."

It would not, I think, be just to consider that in the sentence last quoted, Prof. Weismann proposes a definition of an acquired character as being the reaction of the organism upon an external stimulus, because many passages in our author's writings, and certain well-known facts, seem to show that there are many reactions upon stimuli which result in heritable characters. Thus, at p. 406, he says: "Every one will agree with him (Delmer) that the periodical change of leaf in temperate climates has been produced in relation to the recurring alternation of summer and winter. This is certainly the case, and it cannot be doubted that this character has been fixed by heredity." Heat and cold are external stimuli, and here, if I understand rightly, they are credited with heritable changes in the organism.

Some passages in Prof. Weismann's Romanes lecture tend in the same direction. At pp. 10, 16, and 50 he deals with the case of geotropism, positive and negative; and, if I rightly follow our author, he alleges (1) that geotropism, or the habit of the plant to respond in some particular way to the force of gravity, was not an original character of plants; (2) that it arose, or, in popular parlance, was acquired when plants became attached to the ground; and (3) that it is inherited. Now if I apply to this what is, as I understand, taught by the Professor, I conclude that the physical characters which produce the habit are due to the concurrence of two things, viz. (*a*) the original predisposition and (*b*) an external stimulus, viz. gravity. From this it would seem to follow that if all "acquired characters" are reactions on external stimuli, yet some such reactions are not "acquired characters."

The more I look at the matter, the more I feel it impossible to suppose that all the reactions on external stimuli are "acquired characters." For when I consider the vast part played by air, food, heat, moisture, gravity, and light, all of which are external stimuli on the development of plant life, and as I gather from passages already cited from our author on the production of some qualities, such as size, colour, &c., which are familiarly known to be inherited, I feel it difficult to suppose that it can be thought that all responses to external stimuli are to be considered as incapable of transmission. If I try to arrive at a definition by drawing a distinction between the principal and the minor causes of a change in the organism, or by calling some things conditions and other causes, I succeed no better; for here I should be introducing metaphysical distinctions. There is, so far as I know, no physical or logical distinction between principal and minor causes, or between cause and conditions in the case of two or more constituent parts of a cause, each of which is necessary, and none of which is by itself sufficient.

But this line of thought carries me further. Prof. Weismann ("Essays," vol. i. p. 411) deals with the case of "spontaneous characters, such as extra fingers or toes, patches of grey hair, moles, &c.," which he says may be transmitted. But do we know (*i.e.* do men of science know) that no external stimulus has had anything to do with the production of, say, a mole? It is one thing not to know affirmatively that this is the case, and another thing to know that it is not the case. Is the distinction between characters which seem to be due to an external stimulus and characters which seem to be spontaneous, one which is the subject of accurate scientific knowledge? Seeing that we only know organisms when subject to stimuli, do we know what they would be or would produce without stimuli? Have we any scientific knowledge of the organic world as developed entirely *ab intra* and independently of any external influence, *i.e.* of what plants and animals would be without light, heat, food, air? If we have not, then the distinction relied on may be perfectly true, but is of no value for scientific reasoning at the present day.

Then it has occurred to me to inquire whether I can make a safe distinction between the two kinds of change by reference to the development of the embryo. If a mole were to be found on the arm of a child at birth, we should be more inclined to regard it as spontaneous, as due to no external cause, than if it appeared in mature life. The embryo in the case of a child is no doubt protected from many external stimuli; but surely in the case even of the placental mammalia it would not be safe to aver that the embryo is protected from all external stimuli. In the case of an insect, the greater part of its development takes place under an exposure to external influences as complete as that of the adult insect; in the case of reproduction by gemmæ of multicellular animals, the protection must, I suppose, often be small or nothing at all; and in the case of the reproduction of the lower plants from gemmæ or from protonema, or of the higher plants by buds or from suckers, the embryonic condition, if it can be spoken of at all, is, I suppose, hardly distinguished as regards the influence of external stimuli from any other part of the career of the organism; so that I find myself unable to reach clear ground for the distinction between spontaneous and non-spontaneous variations.

But there are passages, to one of which I have already referred, which seem to suggest that the definition should be framed by reference to a distinction between a direct and an indirect influence, and that the definition should run thus: an "acquired character" is a reaction of the organism upon the direct influence of a stimulus, leaving reactions upon indirect influences to be treated as non-acquired characters. If so, what is the precise meaning of the word "direct" as applied to the influence? Does it refer to the repetition of the stimulus—so that a single change of climate would be a direct, and a repeated change of climate an indirect influence? Or does it refer to the supposed difference between influences operating on the somatic part of the organism and those which the organism itself exerts on its germ plasma? If so, I ask how is this ascertainable as a physiological fact?

Another limitation on the proposition that the reactions of the organism on external stimuli are acquired characters, I find in the second volume of Weismann's "Essays on Heredity" (English translation, p. 14), where the author, having referred to the characters, such as shape and size of finger-nails, likenesses of features, bearing, gait, handwriting, which are handed down from parent to child, goes on to add: "Characters only acquired by the operation of external circumstances acting during the life of the individual cannot be transmitted." Now, handwriting must, I suppose, be conceived of as a thing dependent on external circumstances: it is influenced by the material on which, the fluid by which, the pen or style by means of which the act is performed; but here the external circumstances have operated during many generations; so that the passage seems to suggest these propositions, viz. the reactions of the organism on external stimuli operating during the life of a single individual are not hereditary; the reactions of the organism operating during the lives of two or more individuals are hereditary. But such is not, I suspect, really the meaning of the author; it would be inconsistent with what he says at p. 40 of the same volume, where he says that the supposed increase of the musical sense "in the course of generations" by the exercise of the art can only have occurred on the supposition "that these modifications of an organ which are due to the exercise during the individual life can be transmitted to offspring"—a supposition which Prof. Weismann says "a close examination does not allow us to admit."

Another limitation on the class of reactions upon external stimuli constituting "acquired characters" is suggested by what I conceive to be Prof. Weismann's latest utterance on the subject, in his work "Das Keimplasma" (Jena, 1892). At p. 514 I find him saying—"By the term acquired characters I understand those which do not exist originally in the germ as tendencies, but first arise through peculiar influences which operate upon the body or particular parts of it. They are the reactions of these parts upon some external influences lying beyond the necessary conditions of development."[1] In the first of these sentences it seems to me that the Professor is not so much offering a definition as announcing a theory; for except by the inquiry whether the character is or is not heritable, I suppose that there is no means of ascertaining whether or not a change in the organism is due to a tendency in the germ.

But the second sentence seems to suggest a definition of "acquired characters" free from many of the difficulties we have hitherto encountered. They do not include all reactions of the organism on external stimuli, but only such as lie beyond the necessary conditions of development. Everything then turns on the meaning of "necessary conditions of development." What are necessary conditions of development? Let us take a tree which has put forth its leaves, its flowers, its seeds, in usual fashion, but which, having lost a limb by the saw of the gardener, and has thrown out around the wound that growth of new wood and bark with which we are familiar. The air, the sun, the soil are all external influences, and all necessary conditions of the development *which has actually occurred*, and so was the saw of the gardener. If we take the development which has actually occurred, every condition which led up to it was necessary, and each was as necessary as the other. Take the case narrated by Sir James Paget, of a fir tree which for a hundred and fifty years threw out successive annular growths over the part of its trunk from which a large piece of bark had been stripped off. ("Address to the Pathological Section of the British Medical Association," 1880, p. 15.) Were these rings part of its development, or were they not? If they were, the knife or saw was one of its necessary conditions. Most persons will reply that the saw was no necessary condition of the development of the fir tree, and that those only were necessary conditions without which the fir tree could not have lived.

If we consider what are the necessary conditions for the development of the seed of the fir tree, we can probably ascertain them; but the doctrine of evolution and the doctrine of the non-heritability of acquired characters will carry us back further, viz. to the primordial organism, and we must ask what were the necessary conditions for its development.

If this organism were supposed to have in itself a pre-existing law according to which it sought development, a contingent destiny inherent in its nature, then I can well understand how the conditions which satisfy that contingency, the circumstances which allow of that development might be said to be necessary to it. But if the organism have no such law and no such destiny, but instead thereof has only a capacity to vary in every possible direction, and if all the course of its actual variation be due to external circumstances operating by means of natural selection, then it seems to me that no one external thing can be said to be more essential to its development than another. The germ might have found itself in a different soil, in a different climate, exposed to different air, and then the development of the germ would have been different. There was no *à priori* necessity that it should be exposed to the particular conditions to which it was, in fact, exposed, or to any other particular conditions. If, therefore, we start from the actual development of an organism, and look back on the past, all the conditions which have led to its existing state are necessary; if we start from the germ prior to all development, and look to the future, then no given condition can be said to be necessary to its development, but all are contingent.

It is suggested that no influence lying beyond the necessary conditions of development can at any time have produced any heritable character, however long may have been the course of development. It seems, therefore, that in order to ascertain what conditions are necessary to development, we must go back to the amœba or ascidian or other primæval parent of our race, and we must conclude that those characters only will be transmissible by the human parent, which were reactions on the necessary conditions of the development of the primæval ancestor. Have we any scientific means of ascertaining what these conditions were, and so of ascertaining what characters are now heritable? Nay, if we adopt the evolutionary hypothesis, and believe that at least all existing animal organisms have sprung from a single parent, do not the diversities of the existing forms show that no one set of external circumstances were necessary conditions of development, but that the conditions consistent with development were infinite, or all but infinite, in number?

A further difficulty arises in my mind from a passage on the next page (p. 515), where I find our author mentioning wounds and mutilations as constituting one category of acquired characters. It is difficult to reconcile this with the statement of the Professor, in several passages, that acquired characters are reactions of the organism; for surely a wound is not a reaction of the organism, whilst the growth of the organism consequent on the wound—*e.g.* the growth of new wo

[1] It may be well to give the passage in the original: "Unter erworbenen Eigenschaften verstehe ich solche, welche nicht als Anlagen schon in Keim vorhanden sind, sondern erst durch besondere Einwirkungen, die den Körper oder einzelne Theile desselben treffen, enstehen. Sie sind die Reactionen dieser Theile auf irgend welche, ausserhalb der nothwendigen Entwickelungsbedingungen liegenden äusseren Einwirkungen."

and bark round the stump of a branch sawn off, is a reaction of the organism on the action of an external influence. It seems, therefore, fair to suppose that when our author speaks of a mutilation as an acquired character, he means the growth of the organism consequent upon the mutilation. But if so, a difficulty appears to arise; for the tendency to repair a wound is heritable, and therefore it seems difficult to suppose that the Professor would treat of it as not heritable. It may be said that the parent has the actuality of the repair, the child only the possibility of repairing; but this is, I suppose, all that can ever be expected of inheritance as applied to contingent reactions—*i.e.* reactions which only arise under peculiar circumstances. There can, I suppose, be no more characteristic heritable reaction than that of the pollen on the ovule, and of the ovule on the pollen; these reactions have taken place in the parent plant, but in the offspring they are originally potentialities, tendencies, contingencies, and they are converted into facts in the event, and in the event only, of the meeting of the pollen and the ovule.

Or take, again, the secretion of the gastric juice in response to the presence of food in the stomach. The parent has taken food, and the reaction has taken place; but the infant inherits, I suppose, the capacity to secrete and not the counterpart of the actual secretion of the parent.

It would seem that there is no essential difference between these three cases. The parent transmits the power to repair a wound, but not the actual reparation of a wound: it transmits the power of fertilisation, but not the fertilised ovules: it transmits the power to digest, but not the already secreted gastric juice.

The emphasis which Weismann has laid on the case of wounds and mutilations would suggest that his doctrine might be thus paraphrased: when an organism is endowed with a capacity, or, to use his word, a predisposition, to react in response to given stimuli, and has so reacted—then what the organism transmits to its progeny is the capacity or predisposition, and not the actual result of the reaction.

It is impossible to doubt that some characters of an organism are hereditary; that others are not, and that the ascertainment of the dividing line between the two classes is of the highest moment to the study of biology; and to Weismann we owe a debt of gratitude for having called pointed attention to this matter. I have at times been tempted to wish that men of science had applied themselves to ascertain the two categories of characters, and then by a careful induction had proceeded to learn the law of heredity without regard to any hypothesis or theory—without reference to germ or soma. But this is not the course which in fact has been taken; and therefore it seems highly necessary to inquire what is the precise meaning of the terms of the proposition affirmed by the one side, and denied by the other.

I conclude this, I fear, too lengthy paper with two questions: (1) Are the conditions which I have suggested as essential to a good definition correct ones; if not, in what are they erroneous? (2) What is the true definition of the words "acquired characters" in the present controversy which satisfies these conditions?

Discontinuous Motion.

THE old theory of the motion of solid bodies through a frictionless liquid supposed that the liquid flowed according to the electrical law of flow. This theory was found to be unsatisfactory, because it makes the pressure negative when the velocity of the solid exceeds a certain critical value.

The theory of discontinuous motion removes the above objection, but is open to others of a different kind. Assuming for the sake of argument that the two theories give correct results when the velocity of the moving solid is respectively less and greater than the critical value, the theory of discontinuous motion ought to be capable of explaining the transition from one kind of motion to the other, and how and why it is possible for a vortex sheet to be called into existence when the critical value of the velocity is exceeded.

Although vortex sheets and other motions involving molecular rotation cannot be generated in a frictionless liquid by a conservative system of forces or by operations performed on the boundary, yet it is easy enough to produce such motions by ordinary mechanical agencies. If a mixture of ice and water be stirred up and the ice allowed to melt, the liquid will acquire molecular rotation owing to the presence of the particles of melted ice, even though it is absolutely devoid of viscosity. So also if liquid at rest were separated by an indefinitely thin horizontal plate, and the upper liquid were set in motion with horizontal velocity V and the plate were removed, the surface of separation would be a vortex sheet. But the production of motions of this kind requires methods of a somewhat artificial character, and it is difficult to see how they could be set up by a solid whose velocity is allowed to increase gradually from zero to some magnitude greater than the critical value. In fact, I entertain very little doubt that the final motion of the liquid would be quite different from what the theory of discontinuous motion would indicate.

There is, however, a further point, for there are strong grounds for believing that vortex sheets are unstable. No general proof of this proposition appears as yet to have been given, but in every case that has been examined the theorem has been found to be true, (i.) when the liquids on either side of the sheet are identical, (ii.) when the densities of the two liquids are different, but no bodily forces such as gravity and the like are in action. If, therefore, steady discontinuous motion existed at any particular instant, the probabilities are that the motion would be unstable, and the region of dead water in the rear of the moving solid would break up and be changed into a region of turbulent motion. The pressure in the rear of the solid due to this turbulent motion would be different from that of the dead water, and it is therefore not surprising that the theory of discontinuous motion should furnish results which do not agree very well with experiment.

We must also recollect that a frictionless liquid is an ideal substance which does not exist in nature. All fluids are more or less viscous; and it is just at the point where the pressure would otherwise tend to vanish and change sign that we should anticipate the effect of viscosity would appear, and prevent this state of things from taking place; and I believe that many of the difficulties which have arisen in connection with this subject are due to the fact that the effect of viscosity has been overlooked. A vortex sheet cannot exist in a viscous liquid; and if by any artificial means one were produced, it would immediately disappear, and molecular rotation would be propagated into the surrounding liquid. On the other hand, in a viscous liquid, molecular rotation requires no artificial means for its production; for a viscous liquid cannot move without molecular rotation, except in the single case in which the liquid moves like a rigid body having a motion of translation alone. In all other cases, if irrotational motion existed at any particular instant, the motion would immediately cease to be so, and molecular rotation would instantaneously be generated.

Unfortunately the equations of motion of a viscous liquid are so intractable that very little progress has been made in applying them to the solution of hydrodynamical problems. By means of Oberbeck's solution (*Borchardt's Journal*, vol. lxxx.) for the steady motion of translation of an ellipsoid in a viscous liquid, it can be shown that the above difficulties do not arise when viscosity is taken into account; but since the integration of the equations of motion proceeds upon the assumption that the squares and products of the velocities may be neglected, the solution is inapplicable except in the case of slow motions like those produced by the small oscillations of pendulums. The solution gives no information as to what will happen when a disc is moving through a liquid with a velocity of several feet per second.

Capacity for Heat.

IN the course of some writing upon which I am now engaged, I have constantly to refer to the *capacity for heat of certain substances as compared with the capacity for heat of an equal volume of water*.

The phrase given in italics is a most clumsy one, but I know not how (accurately) to convey the same idea in a shorter way. "*Capacity for heat of unit volume*" has been suggested; but I think that a little reflection will show that it does not express accurately the exact meaning.

Specific Heat × *Specific Gravity* gives the numerical value required, but cannot be regarded as a definition. There can be no doubt but that a concise expression is wanted. In calorimetry it is often of greater importance to the experimenter to onsider the capacity for heat of volumes rather than the capacity of masses. In the course of a communication which I made to the Physical Society of London, at their last meeting, I appealed to the Fellows present to supply me with the missing phrase. In the discussion which followed the paper, this matter was only incidentally referred to; but, although I think that there was a general agreement as to the want, unfortunately the meeting closed without coming to any conclusion as to the best method of supplying the deficiency.

Will some of your readers help me in this matter?

The Swallowing of One Snake by Another.

THE snake incident, described in NATURE, October 25 last, page 620, as having occurred in the reptile-house in the Zoological Society's menagerie, recalls to my mind two similar cases, recorded in the same periodical, vol. xxx. July 3, 1884 ("A Cannibal Snake," by E. H. Evans), and July 31, 1884 ("The Swallowing of One Snake by Another," by C. R. Osten-Sacken). The first case was observed in Java, the other was witnessed by me in Washington, D.C. In the latter case one of the snakes, although three-quarters of its length had already been engulphed in the other, succeeded in getting out, apparently unhurt, as it remained alive and well in the cage a long time afterwards.

In the *Figaro*, July 26, 1894, I found still another instance of the same kind, which happened in the Jardin d'Acclimatation in Paris. A large snake, while attempting to swallow a rabbit, was interfered with by another one, and passed with the rabbit into the body of its comrade of captivity ("L'un des deux passa à la suite du lapin dans le corps de son camarade de captivité"). C. R. OSTEN-SACKEN.

Heidelberg, Germany, October 28.

ON RECENT RESEARCHES IN THE INFRA-RED SPECTRUM.[1]

I PRESENTED to the Association in 1882, at Southampton, an account of some researches made by means of the bolometer, in the infra-red spectrum, formed by a glass prism; but though these labours have continued with occasional intermission during the past twelve years, it is for reasons, which will be explained later, only within the past three years that any notable advance has been made, and only within the past twelvemonth that such a measure of success has been attained as justifies the present communication.

This is not the time to give any historical account of discovery in the infra-red, but all those interested in the subject know that the first investigator here was Sir William Herschel, whose observations consisted essentially in finding that there was something which the eye could not see in a region which he proposed to call the "thermometric spectrum." His distinguished son, Sir John, made a curious anticipation of later discovery by indicating, though crudely, that this invisible heat was not uniformly distributed, and a similar conclusion was reached in an entirely different manner, through the thermopile, by the too early lost Melloni. So ignorant, in spite of these investigations, of those of the elder Draper and of the elder Becquerel, were we till lately, that when, quite within my own recollection and that of most of you, Lamansky in 1871 published, from his observations with the thermopile, a crude little illustration showing three inequalities in the energy curve, universal attention was excited by it among those interested in the subject.

Among other minds my own then received a stimulus which turned it in this direction, and having, as it seemed to me, exhausted the capacities of the thermopile, I invented an instrument for continuing the research, which was afterwards called the bolometer, and with which, in 1881, at an altitude of 13,000 feet upon Mount Whitney, I found spectral regions hitherto unreached, and whose existence had not been suspected.

[1] A paper read to Section A of the British Association, at the Oxford meeting on August 11, by S. P. Langley.

I returned with a strong impression of the prospective importance of this discovery, and laboured at the Allegheny Observatory in improving all portions of the new method of research, especially of the bolometer and its adjuncts, with the twofold object of obtaining greater sensitiveness to heat, and greater precision in fixing the exact point in the spectrum where the change of heat originated. With the former object such a degree of sensitiveness was at that time reached, that the bolometer indicated a change of temperature of $\frac{1}{100000}$ of a degree Centigrade, and with the latter, such precision that it was possible to fix the relative position of a line, not merely with a possible error of a considerable fraction of a degree, such as Lamansky's determination is evidently subject to, but with a certainty that the error would be within a minute of arc. The range of the apparatus in wave-lengths was almost unlimited as compared with any other process, and both its sensitiveness and its possible precision seemed to be at that time notable as compared with previous methods, for a great advance was made on anything done before with the thermopile, when the presence of the well-known "D" line of sodium was rendered sensible (though barely sensible), even as a *single* line, by the change of temperature. The sensitiveness was also, as has been said, accompanied with the possibility of unusual precision. The results of this labour were laid before the British Association in the communication already alluded to, and which exhibited ten or twelve inflections of the curve in the portion till then almost unknown, which extends from a wave-length of of 1μ to a wave-length of nearly 3μ, at which point the glass prism then used became wholly opaque to radiation. The positions of these inflections were fixed with a precision quite impossible to the thermopile, but this exactness was only obtained in practice by a process so slow as to be almost prohibitory; and with this apparatus the writer personally made in those earlier years such a number of observations as he hardly likes to recall, so disproportionate did the labour inherent in this method seem to the final result.

The justification of this labour seemed to lie in the fact that it does not appear that photography has ever rendered anything much below a wave-length of 1μ—anything, at least, which has been reproduced for publication in a way which gives confidence that we are in touch with the original. The processes which involve the use of phosphorescent substances have given some indications of lines considerably below 1μ, but it is safe to state that the work which has just been referred to as communicated to this Association in 1882, presents almost the only indications which we have possessed, even up to the present time, about the lower infra-red solar spectrum.

Now the curve which was given, even in the later Allegheny observations made with the rock-salt prism, contained but a dozen inflections below the wave-length of $1{\cdot}5\mu$, and these inflections, with their correct prismatic and wave-length positions, represent, I think, most of our present knowledge in these regions even to-day.

To understand the method by which there were attained, but only at this great cost of labour, results till then unreached, it may be repeated that the bolometer had been rendered more sensitive than the thermopile, but that it was capable of being pointed and its position in the spectrum being measured, only by a tedious process which has been exclusively used till lately (but which that presently to be described advantageously replaces). Whichever process is used, when the bolometer thread touches a cold line in the spectrum (since what is black to the eye is cold to it), a larger current flows through the galvanometer, and the spot of light marking the needle's motion is deflected through a certain number of degrees.

From this point forward, the new process, whose results I am about to have the pleasure of bringing before you, differs widely from the old. In the old, two observers at least are engaged: one, who notes that reading of the micrometer or of the vernier, which fixes in angular measure the exact part of the spectral region whence (though nothing is visible) a thermo-electric disturbance has proceeded; and another, who simultaneously notes through how many divisions of the scale the spot of light from the galvanometer mirror is deflected by the same electric disturbance. The process may be compared to a groping in the dark, and it was only by these means that the considerable inflections of the energy curve much below the region about 1μ were then fixed by the bolometer, by being gone over again and again, with what seemed almost interminable repetition, and which did in fact call for over a thousand galvanometer readings to obtain the position and amount of each single inflection of the energy curve, with the degree of accuracy which was then obtained, and which was shown in the former memoir.

If it took two years to fix the position of twenty lines by this process, it would take two hundred years to fix two thousand, supposing they existed, and it became evident that if the bolometer continued to be the only means available, new and more effective methods of using it must be found.

New Methods.

About ten years ago a plan was first studied, which has ever since been maturing, by means of which this work could be carried on, not only with far greater rapidity, but with greater certainty, and by an automatic process. The idea in its original simplicity is very easily understood.

In the old process, just described, the deflection of a spot of light upon a scale was read by one observer, while another read simultaneously the position in the spectrum of the cold band, or line, which caused the thermo-electric disturbance.

Now, in imagination, let us take away both the observer at the circle and the one at the galvanometer, and, in the latter case, remove the scale also, and put in its stead a photographically sensitive plate. As the needle swings to the right or left, the spot of light will trace upon the plate a black horizontal line whose length will show how far the needle moves, and how great the heat is which originated the impulse. If this be all, when (under an impulse originated by the movement of the spectrum over the bolometer thread) the needle swings a second time, it will go over the same place; but if the plate have a uniform vertical movement, proportional to the horizontal movement of the spectrum, the combination of the two motions of the needle and the plate will write upon the latter a sinuous curve which will be, in theory at least, the same as the curve formerly deducible only with such pains from thousands of such galvanometer readings.

If we suppose that the movements of the invisible spectrum over the bolometer thread are controlled by clockwork so that this spectrum is caused to move uniformly, and that three movements are, by accurate mechanism, rendered absolutely synchronous with those of the moving plate, it is clear that we shall be able to readily deduce from the photographic curve traced on the latter, not merely the amount of the heat, but each particular position in the spectrum, of the thread of the bolometer, which alone can correspond with any given inflection of the curve.

Thus simple is the theory; but no one had better occasion to know how difficult the practice would be, than myself.

The researches by the old method, and the early attempts to improve them, were interrupted by my acceptance in 1887 of a position which implies the administrative charge of different branches of the public scientific service and of duties largely incompatible with original research. What time could be spared from these was, however, partly employed in elaborating the plan of investigation just referred to. An appropriation had been asked of Government for the establishment, on a modest scale, of an astro-physical observatory in Washington, whose first work should be the investigation of the whole infra-red solar spectrum, by some means which would open that great region to knowledge. It had been asked of Government because it seemed that such knowledge, if attained, might teach us facts about the sun and the absorption of its rays by the terrestrial atmosphere, which there was ground to hope would ultimately lead to results of such importance as to justify this national aid.

These observations were resumed in 1890 on the new system, with the aid of the Smithsonian Institution, which provided larger and more efficient apparatus, whose design embodied the results of nearly fifteen years' study of these subjects.

Pending the provision of a suitable observatory building, an inadequate and temporary one was erected in the Smithsonian Park in Washington, to shelter the apparatus, presently to be mentioned, with which it was designed to commence work while making provision for more permanent scientific quarters (which I may add are still lacking).

Apparatus.

The Foucault siderostat, perhaps the most powerful instrument of the kind existing, was originally made by Sir Howard Grubb, of Dublin, from my indications; but its dispositions have since been considerably modified. A beam from its 20-inch mirror is conveyed through the slit of a horizontal collimating telescope having a rock-salt objective of nearly seventeen centimetres aperture, and of ten metres focal length, to the prism or grating. The prism is of rock salt of corresponding dimensions, worked (by Brashear) with the precision of, and presenting all the external appearance of one of flint glass. It is mounted on a massive spectro-bolometer (as the instrument which supports the prism or grating used in producing the spectrum is called). This instrument includes a large azimuth circle, over the centre of which the prism is placed, and it also carries the bolometer, which registers the spectral heat. The focal length of the image-forming lens, or mirror, is in this instrument much greater than in the first one used, and all parts of the apparatus are correspondingly increased in size and stability. The most important and novel feature is, however, the mechanical connection of the large azimuthal circle carrying the prism, with a distant photographic plate, susceptible of vertical motion, and which latter takes the place of the scale formerly in front of the remote galvanometer, both circle and plate being moved by the same clockwork, which is of such steadiness and precision as to make the two movements as far as possible perfectly synchronous.

To fix our ideas, let us suppose that the slow-moving azimuthal circle carrying the prism revolves through one minute of arc in one minute of time; in which case the spectrum will move horizontally across the vertical bolometer thread at a proportional rate. Now, if the same mechanism which causes this circular motion of the prism, and of the spectrum, of one minute of arc in one minute of time, causes the photographic plate to move vertically before the galvanometer mirror at the rate of one centimetre of space in one minute of time; if there be no allowance to make for changes of temperature in the prism or for like corrections, if the mechanician has done his part in such perfection that everything works as it should, it obviously follows that, under such conditions, during every second of this minute a portion of the spectrum represented by the small quantity of one second of arc, will have glided before the bolometer thread, and that during this same second the plate will have been lifted automatically through one-sixtieth of a centimetre of space.

This is one relationship of time and space in actual use here, though others may be established by the use of the change-wheels with which the apparatus is provided. The essential thing is that the plate shall show with great precision, and even on simple inspection, not only the inflections of the energy-curve there written down, but the exact relative position in the distant spectrum which the bolometer thread occupied at the moment it caused the disturbance. In the case assumed, for instance, if we suppose that the record on the plate commences with the part of the spectrum whose angular value is 40°, then, since 1 millimetre corresponds to 6 seconds of arc, and so on, the existence of an inflection on the plate at 30 centimetres, 3 millimetres and seven-tenths of a millimetre, would show that the disturbances originated at the point in the spectrum corresponding to an angular measure of 40° 30′ 22″·2.

If the arm which carries the bolometer is n metres long, and if the thread of the bolometer is $\frac{1}{m}$ metres in diameter, the angular value of the bolometer thread is $\frac{1}{mn}$. At present the linear width of the bolometer thread is not very materially less than formerly, but it is used with a longer arm, and its virtual width is accordingly less. In present actual practice (to use round figures) the optical arm carrying the spectrum across the bolometer, is five metres in length; and if the bolometer thread be one-twentieth of a millimetre in width, its angular value is evidently $\frac{1}{100000}$ of the radius of the circle in which it moves, or a little over two seconds of arc. When the heat is distributed over so large an area, that part of it which falls on a thread of given diameter is, of course, proportionately less, so that the greater precision of measurement demands a more sensitive construction of the bolometer, as well as a more accurate mechanism for pointing it. Improvements have accordingly been introduced in the construction of the bolometer, and a need for greater sensitiveness in the galvanometer has necessarily gone with them. This increased sensitiveness has caused increased liability in the latter to both systematic and accidental perturbations, and the elimination of these has been found the most formidable difficulty of the whole process. It has been effected, largely, by placing the whole apparatus under constant temperature conditions.

I take pleasure also in acknowledging the advantage I have found in using both Prof. Boys's quartz threads and the extremely small mirrors which he, I think, first advocated in connection with the well-known form of galvanometer due to Lord Kelvin. These and other collective improvements made in the bolometer and in the galvanometer, have now made the former sensitive to changes of temperature in its strip which are demonstrably less than 1/1,000,000 of a degree Centigrade.

These are the principal pieces of apparatus, though I should mention that a method has been found by which the very large salt prisms used can be preserved in perfect polish while exposed to all the usual casualties of observation. The actual prism in most frequent use was made from a block of salt exhibited at the World's Fair by the Russian Government, and presented to the Smithsonian Institution by its Commissioners. It is about eighteen centimetres, or over seven English inches, in height.

Before entering upon a description of the results obtained, I desire permission to speak of the aid I have received from the gentlemen whose assistance I have been fortunate in securing: first, to Dr. Hallock, then to Prof. Hutchins, Mr. Hubbard, and Mr. C. T. Child, and lately to Mr. F. L. O. Wadsworth and Mr. R. C. Child; the imprint of the labours of the two latter gentlemen being upon almost all the details of the more recent work.

Results.

Let us recall that the infra-red spectrum from a rock-salt prism, such as that used here, is extremely contracted as compared with one from flint, and still more contracted as compared with the wave-length scale. The portion of the spectrum presented by photography reaches a little below the band whose wave-length is about 1μ, and this was asserted by one of the most eminent living authorities on the subject (Dr. John W. Draper), when the writer commenced this work fifteen years ago, to be the absolute end of the heat spectrum. The writer has, however, since carried his investigations by direct measurement to five or six times this wave-length, and by indirect measurement much farther still, though what is here now exhibited does not go beyond a wave-length of about 4μ. The invisible heat spectrum of a 60° rock-salt prism through this great wave-length, includes only somewhat less than two degrees of arc, and the first of these degrees contains the greater proportion of the energy.

On referring to the illustrations exhibited to the Association in 1882, or even to later publications of results obtained by rock-salt prisms, though with the old method, it will be seen that there are shown in the latter publication about a dozen measured inflections of the energy curve below $1\mu{\cdot}5$, and it may be remembered that this curve was obtained only by two years' assiduous labour.

We have now before us three energy curves obtained by the new method, each exhibiting the whole infra-red spectrum under examination, with about a hundred inflections. These curves are nearly, but not exactly, similar.

The three were obtained in the same day, each from an entirely independent observation, so that each has given, in a fraction of a day, many times the results previously obtained by two years of labour, and, as it will be later shown, has given these results with a notable gain of accuracy.

But this is not all. These three curves have been taken with a rapid movement of the clockwork and a brief swing of the galvanometer, so as intentionally to suppress all minor inflections and to introduce only the leading features of the spectrum, as shown in eighty or a hundred of the leading inflections (lines), or groups.

This new bolometric method has, however, as will be shown later, a capacity of resolving these into nearly twenty times that number, the minor inflections having been thus designedly suppressed here at first, to better show the character and position of the principal ones. All these energy spectra, by the new as by the old method, are, of course, subject to the slight changes due to invisible clouds constantly passing before the sun, which, with the change of the sun's altitude, and of the consequent lengthening path of its rays, prevent any one of them from being exactly like the other; while, at the same time, everyone here may satisfy himself by direct inspection of the results before him, that there is scarcely any single one of their inflections which is not reproduced in the other two, in exactly the same place, though probably not exactly in the same degree; and when we take different spectral traces, made at different hours of the day, and even on different days of the month—traces which are absolutely independent of each other—and superpose them, experience shows that we may expect to see such an agreement as that in the three here chosen at random for illustration, or in the more detailed one, where the relative probable error is less than one second of arc. Three such traces only are here given (to prevent confusion), but if we follow these coincidences through not three, but ten or more plates, we may well judge (since there seems no possibility here of systematic error) that a result, which all confirm, is reliable, and that, on the other hand, a single inflection on one plate, which the other nine unite in repudiating, is due to some fortuitous cause.

But there is still a higher certainty to be obtained, by a method independent even of comparison or the exercise of judgment. It is founded on the well-known process of composite-photography, where, in photographing the successive members of an assemblage of persons, having similar general characteristics, as of race, character or education, the individual disappears, and the normal type alone remains. In order to apply this method to such results as ours, however, another step in the process must be introduced, and this is an interesting one, for the energy curve itself, however valuable, is a comparatively unfamiliar method of showing variations in the energy, which we are all alike used to seeing in the visible spectrum given by linear representations, and not by a system of inflections.

In describing this new step, which is to give us a *linear* spectrum in addition to the original curve, it will be desirable to also give evidence of the statement now made, that the present method is capable of recording far minuter inflections than those shown in the curves here exhibited, which, as has just been stated, have been taken only for the purpose of illustrating such more important features, as can be seen and verified by the audience, and especially for showing the agreement of independent observations. The evidence of the capacity of the apparatus to show this detail will best be illustrated by applying our purely thermometric method to some well-known lines in the visible spectrum, such as the familiar "D" lines of sodium. I have already stated that ten years ago the bolometer was barely able to distinguish this as a *single* line. At the present time our little thermometer, as you here see, now shows not only the two "D's" as separate lines, but the nickel line between them. First we have the complex energy curve (Fig. 1), where we see successively the inflections due to the motions of the galvanometer caused by the cold in D_1, then to the smaller chill from the nickel line (aided perhaps by that from some of the close atmospheric lines), then the chill from D_2.

Immediately below this curve is the more familiar linear representation of the same subject (Fig. 2). Now this linear representation, it is most important to observe, has been obtained, not by drawing, but by the subsequent application to the curve of an automatic process, by means of which its indications are reproduced by photogravure, as separate lines, while by the same automatic process the most complex spectral curves can be rendered into their linear equivalents.

I have no space to enter here on a description of this process, further than to say it is effected by means of a systematically distorted image of the curve, obtained by a special combination of spherical and cylindric lenses. You will see, on minute inspection, that the inflections of the galvanometer curve have been slightly "loaded," to produce a more effective contrast of light and dark. Except for this, which can in no way affect the position of a line, but only its intensity, the whole process is as absolutely automatic as any photograph of the visible spectrum.

This thermograph of the "D" lines has been chosen to indicate the grasp of this new thermometric method, by applying it to the test of an object in the visible spectrum, with which every physicist here is doubtless familiar. He may then be invited to recall that the distance between the "D's" in a rock-salt 60-degree prism is about eleven seconds of arc, and to observe that two lines about half this distance apart are here shown as sharply divided by this thermal method, as, for instance, are the components of the double star *a* Geminorum by a three-inch achromatic. Obviously, then, our method could indicate the existence of two lines, little, if any, more than one-quarter the distance between the "D's." Lines 3″ or less apart can then evidently be indicated by this method, even in its present stage of development.

And now, returning to what has been said about the evidence obtainable as to the perfect coincidence of these inflections in different energy curves obtained at different times, and to the consequent evidence that each inflection so given is real, and not the product of an

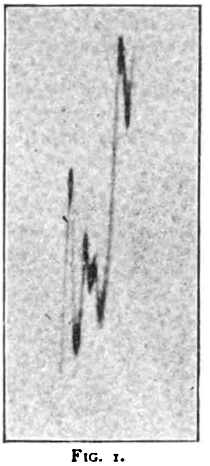

FIG. 1.

$_2D_1$

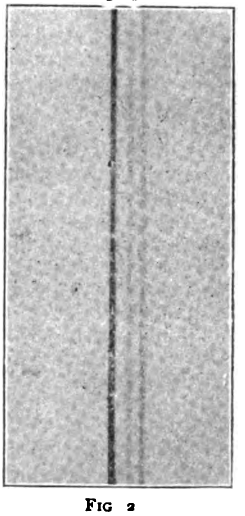

FIG 2

accidental variation in the curve, we may conceive that from any number of such independent curves, any number of such linear representations of the spectra have been obtained; for example, that ten such linear representations of the whole spectrum as are here given of the D lines only, have been so found from ten complete energy curves taken on as many different days. From these ten linear representations, by the well-known processes of composite photography, *one* final photograph of the spectrum is formed, and on this it is evident we may expect to find only what is permanent and not what is accidental, granting that a rare accident may have introduced an occasional abnormal deflection.

Now, considering that the part of the infra-red solar spectrum of rock-salt under review extends through nearly two degrees, or 7200 seconds, and that we have just seen by the illustration of the D lines that lines 3 inches apart can be thus divided, we may see for ourselves that, at any rate, over 2000 lines, if they exist, can be mapped. But these lines do exist, the whole of this new region being apparently as intimately filled by them as the visible spectrum by the Fraunhofer lines. In further evidence of this, here is a portion of the lower spectrum in the comparatively unknown part extending from $\lambda = 1{\cdot}4\mu$ to $\lambda = 2{\cdot}2\mu$ including the great band Ω shown as a single inflection in my first communication to this Association, but here resolved into thirty or more subordinate lines (Fig. 3). This illustration includes a part of the new region discovered on Mount Whitney in 1881; and in the small portion here exhibited, you may see that about 200 lines are discriminated.

I am now trying to bring what may be called the first stage of the long labour, a portion of which is here described, to a close, this first stage consisting chiefly in the discovery of, and mapping the relative positions of new spectral lines.

I will only refer to what it seems to me the second part of this work is likely to be, and to the different kind of interest which may not improbably belong to it, from that which belongs to this, the first.

We are thus far in the position of early students of the visible spectrum, who simply drew the lines they saw, without inquiring into their meaning. Nevertheless, to have discovered and mapped a great number of these lines is only a beginning, for their real value lies in their interpretation, and this is still chiefly to come. As to the possible importance of this interpretation, it is not enough to remind ourselves that three-quarters of the whole energy of the sun exists here, and not in the upper spectrum. We must remember also that while, as a rule, in the upper and visible spectrum a great proportion of the lines are caused by absorption in the solar atmosphere, and a perhaps smaller portion by telluric absorption, here, on the contrary, we are led, by everything we already know, to expect that the great telluric absorptions on which meteorological predictions and other immediately practical interests depend, may be expected to be found, and it is on the comparison of these energy curves taken at different periods of the year, and at different altitudes of the sun, that those who are engaged in the work see good cause to hope for important results in the future.

Before I conclude, let me present a collective view of the field in which work has been going on in these later years at the Smithsonian Observatory, on the same scale, with the visible spectrum. I say "on the same scale," meaning, not on a wave-length scale, which expands the invisible at the expense of the visible, and not on a prismatic scale alone, which expands the visible at the expense of the invisible, nor even on such a logarithmic one as that proposed by Lord Rayleigh, but on a conventional scale, which I will ask you to tolerate, as it is simply meant to show the actual extent and importance of the region covered here as compared with that known to Newton. In this illustration, with which I close my remarks, the mean dispersion throughout the invisible rock-salt spectrum, as far as 4μ, is taken as the standard, and both spectra are laid out on that common scale. On the left is the visible spectrum known to Newton; next this, is the region known through photography, now extending a little beyond the band, $\rho\,\sigma\,\tau$, which marks what at the time these researches were commenced, was considered by the then most distinguished investigator, in the infra-red, the end of the heat spectrum. Beyond, and on the right, is a part of the new regions of the spectrum developed by the bolometer, and of which charts may be shortly expected on the scale of which a specimen in detail has just been shown.

I cannot close this statement without expressing the gratification with which I have laid it before the same body that listened to that made on the same subject twelve years ago, or my sense of my good fortune, in doing so before an audience in which I recognise many of the same eminent men who so kindly received that first presentation of these researches.

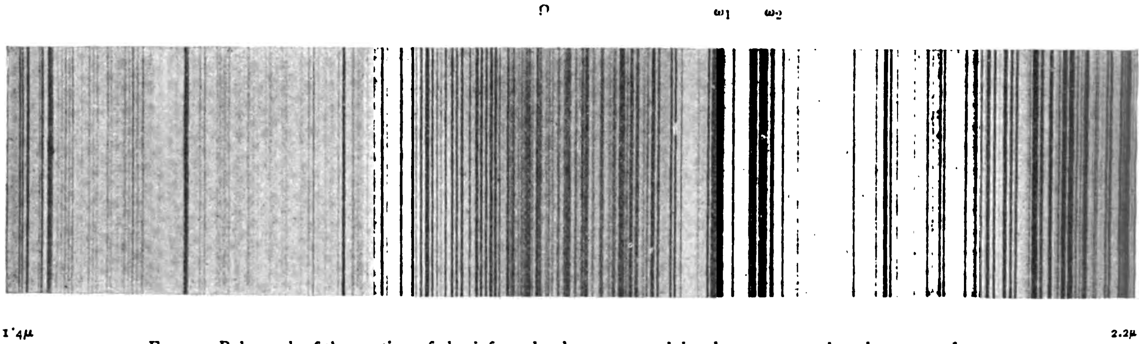

FIG. 3.—Bolograph of the portion of the infra-red solar spectrum lying between wave-lengths 1·4μ and 2·2μ.

THE TREATMENT OF DIPHTHERIA BY ANTI-TOXIC SERUM.

FOUR years ago Prof. Behring published his remarkable paper "On the mechanism of immunity against experimental diphtheria in animals." In this memoir the author stated that it was possible to immunise animals against the diphtheria bacillus by the injection of cultures attenuated by heat or the addition of 1 in 500 trichloride of iodine to the cultivating medium. The same result could be obtained by the inoculation of the pleural exudation of animals dead of experimental diphtheria, or by the injection of chemical compounds, such as trichloride of iodine, after inoculation of virulent diphtheria-bacilli.

Behring's most important discovery, however, was that the serum of animals immune against the bacillus of diphtheria and its poisons had the power of "destroying" in vitro and in the animal body the chemical poison secreted by this bacillus; and that animals, after a mortal dose of diphtheria poison had been injected, could be not only immunised, but actually cured, by the introduction into their system of the serum of animals immunised against the specific bacillus and its poisons. In a further series of researches he found that the serum of such animals possessed this power to a most remarkable and almost incredible degree, and that the therapeutic value of this serum increased up to a certain extent with the amount of diphtheria-toxine which had been introduced into the system; whilst, on the other hand, the same toxine injected in too large quantities might cause the serum to lose its "anti-toxic" property.

Behring afterwards immunised large animals, such as sheep, horses, &c., against diphtheria by the repeated injection of diphtheria-toxine, and he observed that their serum was of great value when injected into human beings suffering from this disease. Before proceeding, however, it may be convenient to discuss these statements at somewhat greater length, and illustrate them by an account of a few experiments.

Let us draw some blood from a horse which has been thoroughly immunised against diphtheria, and decant the serum after its separation. We now take a filtered diphtheria culture, a given quantity of which we know to prove fatal to a guinea-pig of a certain weight in a certain number of hours. Let us divide, for instance, 5 c.c. of this filtered culture into five doses, and inject 1 c.c. into a guinea-pig (A) weighing 500 grammes without the addition of any serum. Four other guinea-pigs of the same weight as the first receive the same amount of toxine and ·1 c.c., ·01 c.c., ·001 c.c., ·0001 c.c. of the horse's serum respectively. The first guinea-pig (A) will die in less than twenty-four hours, but of the others, the three first will recover without any symptom of illness; whilst the last, which has received ·0001 c.c. only, will probably die after some delay. We know, then, that the dose of serum which will protect a guinea-pig of a given weight against a known amount of toxine injected at the same time as the serum, lies somewhere between ·001 c.c. and ·0001 c.c., and, by further experiments, the exact dose may be accurately determined. In this way we may form an idea of the strength of the serum, but we must always remember that the data thus obtained are but approximate ones.

The curative serum may be introduced into the animal the day before the toxine is injected, but, in that case, a much larger quantity of serum will be necessary to protect the animal. If the serum be inoculated at the same time as the toxine, and in a different part of the body, the quantity of serum must also be increased if the curative effects are to be apparent. If some time is allowed to elapse between the injection of the toxine and that of the curative serum, the quantity of serum—in order to be effective—must be proportionately greater; but I have seen animals recover when the injection of the curative serum had been delayed *eleven hours* after the introduction of the toxine, which proved fatal to the control animals in 28–48 hours. In this latter case the dose necessary to cure was 5000 times that sufficient to immunise when the serum was injected with the toxine.

Can any opinion be formed as to the mechanism in which this serum exerts its action? The first explanation which suggests itself is that when the curative serum and the toxine are mixed together in the syringe or in the animal's body, the toxine is either destroyed or simply neutralised, just as the acid in a given solution may be neutralised by an alkali.

Yet there are several facts which negative this opinion, or rather which tend to prove that this destruction and neutralisation of the toxine, if destruction or neutralisation there be, is effected through the agency of the cells of the body. In the first place, if the whole were simply a chemical process, we should expect it to take place with mathematical precision. Thus, if ·001 c.c. of horse's serum did destroy or neutralise 1 c.c. of toxine, this neutralisation should be apparent whether the mixture be injected into a guinea-pig, a rabbit, or a sparrow. But it is not so; on the contrary, it has been found that in certain animals a very small amount of curative serum is sufficient to render harmless a certain amount of toxine when the same amount of serum utterly fails to do so in animals of another species. Even if the same species of animals be used the curative effect will differ in intensity, according to whether the mixture be injected directly into the blood, or into the subcutaneous tissue. Moreover, if a number of guinea-pigs be injected each with the same amount of toxine and varying doses of curative serum, it is of frequent occurrence that some animals will resist when they have received but a very small quantity of serum; while others, which have received equal or even larger quantities of serum, speedily perish. Had we to deal with a simple chemical neutralisation or destruction of poison, identical results should occur in all animals. The action of the curative serum may also be inhibited by weakening the cells of the animal body by the action of bacterial or other protoplasmic poisons. Hence I consider that the term "anti-toxic," which has been used up to the present to denote this property of the serum, is only approximately correct; and I would prefer to substitute the word "curative," until such time as the mode of action of the serum has been accurately determined.

Before speaking of the application of this method to the cure of diphtheria in the human subject, and to the results which have been obtained in the hands of such experimenters as Behring, Roux, Ehrlich, Kossel, Wassermann, Heubner and others, it must be pointed out how the disease in man differs from and resembles that produced experimentally in animals by the subcutaneous inoculation of the bacillus diphtheriæ, or of its poisons. In both man and animals the symptoms are, to some extent, produced (Roux, Behring, Sidney Martin) by the absorption of the poisons secreted by this specific bacillus. But in man the production of these poisons is facilitated by the fact that the bacillus lives on the surface of the membrane, where it is exposed continually to the action of the air entering and leaving the lungs. Now, it has been shown experimentally that the easiest way of obtaining a large amount of diphtheria toxine from the diphtheria-bacillus growing in an artificial medium, is to expose the surface of this medium to a current of air. In the respiratory passages of man these conditions are exactly fulfilled, and the bacillus is able to produce large quantities of toxine. In the second place, the upper respiratory passages are crowded with all sorts of non-pathogenic and some pathogenic micro-organisms, the chief among the latter being the staphylococcus albus and aureus, and the various kinds of streptococci. These multiply on the soil prepared by the bacillus diphtheriæ, and secrete their toxine, which being absorbed, add their poisoning action to the deleterious action of the specific bacillus. In the preceding paragraph, I have drawn attention to the fact that the toxines of another micro-organism will inhibit the action of the curative serum; and there can be little doubt that the toxines secreted by these micro-organisms in man will have the same effects. The formation of the membrane also, and the mechanical obstruction so produced, may in themselves be the cause of death. It must be added, also, that diphtheria is chiefly a disease of the poor, and that in many cases the diagnosis is delayed, and the treatment is not begun until the patient is almost moribund. It is plain, therefore, that in the diphtheria of man we have all the conditions which are favourable to the production of the poison, and the inhibition of the action of the therapeutic serum. Hence we cannot be astonished that the death-rate at the Hôpital Trousseau in Paris amounted during the last six months to 62 per cent. of all cases admitted for this disease, and not treated with curative serum.

An examination of the statistics lately published by Dr. Roux, the eminent director of the Institut Pasteur, will allow us to form some idea of the value of the curative serum when applied to man. The reason for choosing these statistics is that they contain all the elements necessary to enable us to form an accurate opinion. The mortality among 3971 children admitted during 1890–1894, and who were treated on ordinary lines, *i.e.* without curative serum, amounted to 51 per cent., the highest mortality being in 1890, when it reached 59 per cent., and the lowest in 1892, when it fell to 47 per cent. On February 1, 1894, Dr. Roux began the inoculations. As soon as a child suffering from diphtheria was admitted into the Hôpital des Enfants Malades, it received 20 c.c. of serum subcutaneosly, and if no improvement took place, 10 c.c. or more were again injected next day. 448 children were thus treated from February 1 to July 24, 1894, and 109 died, the mortality being 24·5 per cent. At the Hôpital Trousseau, on the other hand, 520 children were admitted during that period, and treated without the injection of curative serum. Of these 316 died, giving a mortality of 60 per cent. This difference is striking enough; but it is even more marked when we come to analyse the results. In the first place, we must eliminate from Dr. Roux's statistics 128 cases which were shown by bacteriological examination not to be diphtheria. This mistake is perfectly legitimate, as it has been shown that without a bacteriological examination, it is impossible to make an accurate diagnosis. The injection of the serum in a doubtful case is followed by no harm, and as the result of the bacteriological examination cannot be known for twenty-four hours, the injection of the serum will, at any rate, prevent the child catching the disease from his neighbour. The mortality among such cases we know to be very slight, and in the statistics of previous years, as well as in those of the Hôpital Trousseau, these cases are included among the cures, so that the proportion of cures appears to be much higher than it really is. These cases being excluded from Dr. Roux's statistics, there remain 320 children in which the bacteriological examination revealed the presence of the diphtheria-bacillus. Of these 20 died on admission, before any therapeutic measures whatever could be employed. Of the 300 other children 78 died, giving a mortality of 26 per cent. We may further divide these into uncomplicated cases, and those in which tracheotomy had to be performed for laryngeal obstruction. Of the uncomplicated cases, the mortality in Dr. Roux's wards amounted to 12 per cent.; whilst at the Hôpital Trousseau, where no serum was used, the mortality during the same period reached 32 per cent. In the preceding years it was 33 per cent. in the wards in which Dr. Roux carried out his experiments.

Turning now to the cases in which tracheotony had to be performed, we find that 49 per cent. of Dr. Roux's cases died. At the Hôpital Trousseau in the same period 86 per cent. of the tracheotomised children perished. Similar results have been obtained in Germany, the mortality in some wards falling as low as 14 per cent. Prof. Ehrlich has shown that the question of time is a most important element, and that the chances of obtaining a cure are infinitely greater when the remedy is applied at an early stage of the disease. The following table, reprinted from the *Deutsche Medicinische Wochenschrift*, will explain this:

Time elapsed from onset of disease to injection of serum.	Number of cases.	Number of cures.	Number of deaths.	Cures, per cent.
1	6	6	0	100
2	66	64	2	97
3	29	25	4	86
4	39	30	9	77
5	23	13	10	56·5

It will be noticed that the number of cures diminishes according to the length of time which has elapsed since the onset of the disease.

It appears to me to be difficult to explain away the results obtained in France and Germany by simply saying that the epidemic has been a mild one; for in other hospitals and institutions in which the curative serum has not been used, the mortality has remained the same, or even increased. In fact, it is plain that the serum treatment of diphtheria is now established on a firm basis, and that it is only right that we should at once give the children in this country the benefit of the results of experimental investigation which has been principally carried on abroad. The British Institute of Preventive Medicine is now taking steps to provide the serum at cost price.

Finally, it is right to draw attention to the fact that although the knowledge of the biology of the diphtheria bacillus, and of the effects of its poison, has been based on the investigations of different observers—French, German, and English—yet the discovery of the curative effect of the serum of immunised animals is the merit of one man only—Prof. Behring, of Berlin.

M. A. RUFFER.

NOTES.

THE Paris Academy of Moral and Political Sciences has bestowed the Audiffret prize of twelve thousand francs upon Dr Roux for his treatment of diphtheria.

A STATUE of Claude Bernard, the eminent physiologist, was unveiled at Lyons on Sunday last, in the presence of a distinguished company.

THE *National Zeitung* states that news has reached Berlin from the Kilima-Njaro district that the German botanist, Dr. Lent, and the zoologist, Dr. Kretzschmar, have been killed, with several of their black followers.

DALZIEL'S correspondent at New York says that a dispatch received from Buenos Ayres gives particulars of a severe earthquake, attended by great loss of life, which occurred on Saturday, October 27, at the town of San Juan de la Fronteza, the capital of the Province of San Juan, in the Argentine Republic. Many of the principal buildings are said to have been destroyed. The shock extended to the towns of La Paz, Cordova, and Rosario. The New York *Herald* of Monday published a telegram from Buenos Ayres stating that two thousand persons have perished in the earthquake at La Rioja, and that twenty thousand are homeless. This alarming report has not, however, been confirmed.

NUMEROUS memoirs have already been based upon the rich collection of Dutch birds brought together by the late Mr. J. P. van Vickevoort Crommelin, of Harlem, and presented, after his death, by his daughter to the Leyden Museum. Ornithologists will therefore welcome the appearance of a complete catalogue of the collection, which has been compiled by Dr. Jentink, the director of the museum, and forms the fourteenth volume of the catalogues of the Muséum d'histoire naturelle des Pays-bas. Nearly three hundred species are in all enumerated, and the majority of these are represented each by a considerable number of specimens. A separate record is given of every individual, notifying the sex and age, the place and date of capture. An explanation which Dr. Jentink furnishes of the exact locality of all the places mentioned should be of material service to the student of the geographical distribution of these birds.

THE London Mathematical Society, having been on October 23 duly registered as a corporation under Section 23 of the Companies Act, 1867, will hold its first general meeting at its office, 22 Albemarle Street, on Thursday evening, November 8 next, at eight o'clock. The meeting is empowered by the Articles of Association to elect a council and officers, to frame bye-laws and to pass resolutions with regard to the affairs of the Society. The following gentlemen have been recommended by the present council (acting under Article 8) for election as the new council and officers for the ensuing session:—President, Major Macmahon, R.A., F.R.S.; vice-presidents, Messrs. M. J. M. Hill, F.R.S., A. B. Kempe, F.R.S., and A. E. H. Love, F.R.S.; treasurer, Dr. J. Larmor, F.R.S.; hon. secretaries, Messrs. M. Jenkins and R. Tucker; other members, Messrs. A. B. Basset, F.R.S., and G. H. Bryan, Lieut.-Colonel J. R. Campbell, Lieut.-Colonel A. J. C. Cunningham, R.E., Messrs. E. B. Elliott, F.R.S., J. W. L. Glaisher, F.R.S., A. G. Greenhill, F.R.S., E. W. Hobson, F.R.S., and W. H. H. Hudson. At the close of the preceding business, an address will be delivered by the retiring President (A. B. Kempe, F.R.S.), on "Mathematics," after which the meeting will proceed to the ordinary business.

DURING this month, the following lectures will be delivered at the Royal Victoria Hall, Waterloo Bridge Road, S.E.:—November 6, Prof. A. W. Rücker, F.R.S., on "The Electric Spark"; November 13, Mr. H. R. Mill, on "Unexplored England"; November 20, Miss Hope Rea, on "The Grand Canary and its People"; November 27, Miss F. Routledge, on "China."

IT is proposed to hold a "Light and Heat Exhibition" at Woodhouse Park next year. The park is situate at Shepherd's Bush, and is, therefore, in direct communication with all parts of London and the suburbs. The exhibits will be classified into eight divisions, viz.:—Gas lighting; electric lighting; various illuminants; heating and cooking apparatus; naval and military; scientific apparatus; photography; historical. The promoters' intention is to hold a series of technical exhibitions on the same site. Further information can be obtained of the Hon. Secretary, Woodhouse, Shepherd's Bush, W.

PROF. W. M. FLINDERS PETRIE will lecture on "Primitive Egypt," at the London Institution, on November 12. The following are among the other lecturers and subjects for the session ending March 4, 1895:—"Wonder-Working Plants," by Dr. David Morris, C.M.G.; "Climbing in the Himalayas," by Mr. W. Martin Conway; "Extinct Monsters," by Rev. W. N. Hutchinson; "The Newtonian Constant of Gravitation," by Prof. C. V. Boys, F.R.S.; "The Fauna of Rivers and Lakes," by Prof. Sydney Hickson; "Twenty Thousand Feet above the Sea," by Mr. Edward Whymper; "The Netherlands," by Mr. H. J. Mackinder; "Waves of Water and Waves of Light," by Mr. A. P. Laurie; "Nerves and Nerve Centres in Action," by Mr. Henry Power; "Comets," by Sir Robert Ball, F.R.S.; "The Germination of Barley," by Mr. A. Gordon Salamon; "Electric Currents in the Body," by Prof. Victor Horsley, F.R.S.; "The Beautiful as seen in Minute Nature," by the Rev. Dr. Dallinger, F.R.S.; "Theory and Practice of Preventative Inoculation," by Dr. E. E. Klein, F.R.S.

For the last week or so the weather in these islands has been of a very unsettled character generally. Several areas of low barometric pressure have reached us from the Atlantic, and were accompanied by strong gales on nearly all our coasts, and in the Channel very rough weather has been experienced, while thunder and lightning have also occurred in many places. The rainfall has been very heavy, especially in the west of Ireland and south of England, where it amounted to nearly four and a half inches during the week ending October 27, while in the Midland counties the fall reached about two inches. Since the beginning of the year the rainfall has about reached, or exceeded, the average in all districts except the Midland counties, where the deficiency is three inches, and the west coast of Scotland, where it is two and a half inches.

PROF. CLEVELAND ABBE includes the following among his notes in the *Monthly Weather Review* for July:—On June 3 a tornado passed north-eastward through the counties of Harney, Grant, and Union, in Eastern Oregon. The most novel feature attending the disturbance was the hail. It is stated that the formation was more in the nature of sheets of ice than simple hailstones. The sheets of ice averaged three to four inches square, and from three-fourths of an inch to one and a half inches in thickness. They had a smooth surface, and in falling gave the impression of a vast field or sheet of ice suspended in the atmosphere, and suddenly broken into fragments about the size of the palm of the hand. During the progress of the tornado at Long Creek a piano was taken up and carried about a hundred yards.

MR. A. TREVOR-BATTYE, about whose safety some anxiety has been felt, has reached Archangel from the island of Kolguef, where he had been studying bird-life. The proposed relief expedition, for which subscriptions had been invited, is consequently no longer necessary.

THE German collector, J. Menges, describes, in the last number of *Petermanns Mitteilungen*, his travels in the Habr Auel district of Somaliland, inland from Berbera. He visited the country in 1882, and gives a detailed account of his routes in pursuit of big game.

THE last Washington letter published by the American Geographical Society states that the boundary line between the United States and Mexico has been resurveyed, and a series of monuments erected along it at intervals for a distance of 700 miles. The field operations for the survey of the Alaskan frontier are also completed, and the height of Mount Logan has been confirmed as 19,500 feet, thus overtopping Mount St. Elias by 1500 feet. Another interesting result of the joint exploration is to show that both these mountains lie within British territory.

THE Indian Reservations of the United States in which the aboriginal inhabitants are secure against aggressive civilisation, are fast diminishing in number and extent. The last number of the *Bulletin* of the American Geographical Society mentions that four million acres of reserved land in the north-east of Utah, containing great mineral wealth, and hitherto the home of the Uncompahgre and Uintah Indians, is about to be opened to settlement, while nearly a million acres in South Dakota are to be withdrawn from the exclusive occupancy of the Indians of South Dakota, Oregon, and Idaho.

CONSUL C. S. SMITH gives an account of the Anglo-German frontier survey in East Africa, in the November number of the *Geographical Journal*. The survey, which was carried from the mouth of the Umba River on the east coast to Kilimanjaro, was effected in 1892, Mr. Smith being assisted by Mr. Imam Sharif, the Indian surveyor, who subsequently accompanied Mr. Bent to Arabia, and Lieut. G. E. Smith, R.E., and the German party with whom they co-operated was under the charge of Dr. Peters. The route by the Umba Valley to Kilimanjaro was found to be a practicable one, and the country traversed was, as a rule, characterised by fertile soil; but the land suffered from the want of settled inhabitants, on account of the raids of the Masai. Consul Smith suggests that immigrants from India be encouraged to colonise parts of the Umba Valley; and if trade is ultimately attracted there, he points out that the seaport of Wasin, although smaller than Mombasa, would be found quite practicable for steamers.

THE current number of *Himmel und Erde* contains a summary of a lecture by the Director of the Statistical Office of Berlin, on the increase of damage by lightning, and on the effect of lightning on the human body. The increase, which is unmistakable, is attributed to various causes, viz. the employment of electricity in various industries, the continual change of the form of the earth's surface by deforestation, drainage, &c., and the impurities introduced into the atmosphere by the growing consumption of coal. Prof. von Bezold has shown, some time since, that for Bavaria the average yearly number of fires caused by lightning amounted to 32 from 1833–43, to 52 from 1844–65, to 103 from 1866–79, and to 132 between 1880 and 1882. While in the year 1855, 134 persons were struck by lightning, and 73 were killed, the numbers thirty years later reached 189 and 161 respectively. It is noteworthy that persons struck by lightning generally perceive neither lightning nor thunder, but have the idea of being suddenly enveloped by fire.

To the facts of fishes out of water and of crabs on dry land we are accustomed, but the recent announcement of the discovery of a flying Copepod is a novelty of which the naturalist has probably never dreamed, though Giesbrecht's beautiful figures of the Naples forms might well have induced the thought of such a possibility. In the current number of the *Zoologischer Anzeiger* (No. 459), Dr. Ostroumoff, of the Sebastopol Biological Station, states that he and his son were coasting along the Khersonese peninsula on a calm clear morning last July, when they noticed numbers of the tiny green Crustacean, *Pontellina mediterranea* (Claus), flying just above the level of the water. "Many of these Copepods were resting on the surface-film, took springs into the air, where they described a long curve, and fell down again upon the water surface." Dr. Ostroumoff traces the origin of this very exceptional habit to a peculiarity in the manner of exuviation that *Pontellina* probably shares with certain other pelagic Entomostraca, *e.g. Evadne, Pleopis*, which cast their skins at the surface of the water "by the help of the air which becomes entangled in (*anhält*) their rejected coverings." We should like to hear something more upon this interesting phenomenon, which involves a complete change in the life conditions of the species. It is difficult, at any rate, to imagine that so light and hairy a form as *Pontellina* can return at will to the water again after once breaking through the surface film.

THE Bunsen flame spectra of the metals of the alkalies and the alkaline earths have been studied by Herren J. M. Eder and E. Valenta, by means of an apparatus which enabled them to make exposures of extraordinary length. The apparatus, described in a paper communicated to the Vienna Academy, consisted essentially of a circular strip of platinum gauze mounted in a slanting position on a nickel wheel. The lower edge dipped into a solution of the salt to be examined, and the upper edge passed through the Bunsen flame. The wheel was kept slowly rotating by clockwork, and the steady and uniform spectrum obtained was photographed. In the case of sodium and potassium no lines were discovered that were not already known from the spark and arc spectra, although the ultra-violet sodium lines of wave-lengths 3303 and 3853 were well rendered. But with an exposure of some thirty hours a large number of new bands appeared in the violet and ultra-violet spectra of the metals of the alkaline earths. They belonged chiefly to the oxides, and consisted partly of double bands arranged pretty regularly on a continuous background. The spectrum of boracic acid, obtained by burning a mixture of coal gas and $B(C_2H_5)_3$ in a Linnemann burner, showed six new violet and ultra-violet bands, which by their general character and their regular distribution correspond to those previously observed in the visible spectrum.

A REMARKABLE instance of the anomalous behaviour of bodies at very low temperatures is given by M. Raoul Pictet in the *Revue Scientifique*. For the preparation of pure chloroform by crystallisation at $-69°$ C. he used two copper refrigerators, of capacities of 2½ and 32 litres respectively. The former being more convenient, it was used for the first series of experiments. About 2 kgr. of commercial chloroform were put into a glass test-tube, placed in the refrigerator, and surrounded by a temperature of about $-120°$, as indicated by a sulphuric ether thermometer. The chloroform appeared turbid at $-40°$ or $-50°$, and was filtered and further cooled. At $-68°\cdot5$ the cooling ceased, and very transparent crystals of chloroform appeared on the walls of the test-tube. The chemically pure chloroform thus obtained was used with great success in the Berlin hospitals, and larger quantities had to be obtained. M. Pictet noticed with great surprise that chloroform, refrigerated in the larger vessel, was cooled to $-81°$ without a trace of crystallisation. To test for experimental errors the small refrigerator was exposed to the same cooling process, and the chloroform crystals plunged into the larger one. But the crystals dissolved at once, though the same thermometer, successively plunged in the two refrigerators, fell from $-68°\cdot5$ to $-81°$, where no crystallisation was going on. Finally, the whole test-tube, with crystals at the walls, liquid chloroform in the centre, and thermometer standing at $-68°\cdot5$, was immersed bodily in the liquid chloroform at $-81°$. The thermometer gradually fell from $-68°\cdot5$ to $-81°$, while the crystals dissolved before the observer's eyes. M. Pictet works out an explanation of this striking phenomena on the basis of the theory of radiation and his own theory of the molecular constitution of solids and liquids, which leads him to the conclusion that heat oscillations corresponding to low temperatures traverse bad heat conductors with greater facility than they do compact and heavy substances such as metals.

THE fifth report upon the activity of the German Imperial Physico-Technical Institute appears in the *Zeitschrift für Instrumentenkunde*. Besides the electrical work, which chiefly dealt with resistances, the principal subjects of investigation were connected with thermometers, manometers, barometers, pyrometers, standard Hefner lamps and photometry, and the physical properties of various kinds of glass. The branch establishment at Ilmenau, in the Grand Duchy of Saxony, has been extended by the addition of a technical school for workers in glass instruments. Among the barometers tested were the aneroids employed by Dr. von Drygalski on his Greenland expedition. It appeared that low temperatures are capable of creating a temporary disturbance in the indications of these instruments. The chief optical work was connected with photometry. As regards the introduction of the Hefner lamp as a standard of illumination, the report points out that Germany is ahead of other countries in possessing a well-authenticated standard of light which answers all technical requirements. Recently the Institute has endeavoured to construct simple and portable photometers for technical purposes. Two such instruments have been constructed and found to work well. The photometry of the arc lamps illuminating "Unter den Linden" at Berlin, was also taken in hand by the Institute. The examination of different glasses related mainly to their solubility in water, which was found to give an indication of various other properties. The electrolytic precipitation of zinc and other metals from dilute solutions was investigated with a view to their preparation in a pure state. The examination of specimens of steel, of chronometer oils, and of coloured thermometer liquids, was among the many tasks allotted to this most useful and many-sided National Physical Laboratory.

IN the Pitt Press Mathematical Series there is no more useful volume than "Arithmetic for Schools," by Mr. Charles Smith.

The Cambridge University Press has published a second edition, in two parts, of Mr. Smith's work. Evidently the book has met with the reception it deserves.

THE importance of experimental work is fully recognised in the agricultural department of the Glasgow and West of Scotland Technical College. We have before us the reports on experiments on the manuring of hay, oats, and turnips, conducted in 1893 on the Home Farm of Cleghorn Estate, near Lanark, and on about fifty other farms scattered all over the south-western counties of Scotland. Prof. R. P. Wright, who directed the experiments, must derive satisfaction from the useful conclusions to which they have led.

THE first part of Mr. J. W. Taylor's "Monograph of the Land and Fresh-water Molluscs of the British Isles," published by Messrs. Taylor Bros., Sovereign Street, Leeds, has just appeared. It would be difficult to speak too highly of the fine coloured plate which forms the frontispiece to the part, or of the 138 well-drawn illustrations in the text. These figures will be recognised by all conchologists as faithful representations of the species they personify. The work is readable, concise, and accurate, so far as it has been published, and the scientific naturalist, as well as the systematic student, will find it useful and interesting.

MR. R. L. JACK, the Government Geologist of Queensland, has issued his report of the progress of the geological survey for last year. We learn from it that the most important work of the year was the production of a geological map of the Charters Towers gold field. The first edition of this map was issued early in the present year, and Mr. Jack does not claim too much when he says that no important centre of mining industry in Australia has been so thoroughly mapped. The underground work has now been completed, and it is expected that a second edition, embodying this work, will shortly be published. With Mr. Jack's report we received a report, by Mr. W. H. Rands, on the Towalla and Marceba gold fields.

WITHIN the past few years the number of students and workers in glacial geology has greatly increased. The third edition of Prof. James Geikie's "Great Ice Age," just published by Mr. Edward Stanford, appeals therefore to a much larger class than when the previous issue appeared seventeen years ago. The work has been enlarged, and most of it has been rewritten. The mass of glacial literature that has accumulated during the last fifteen years or so, has rendered it possible for the author to treat the glacial, and interglacial, deposits of the continent much more fully than in the second edition. The phenomena of existing glacial action in Alpine and Arctic regions, and the glaciation of Scotland, have been revised in the light of recent work, and several rearrangements of matter have been made. An important addition consists of two chapters on the glacial phenomena of North America, by Prof. T. C. Chamberlin. All glacialists will welcome this authoritative account of the glacial accumulations of Canada and the United States. It increases the value of what has always been a valuable treatise.

THE additions to the Zoological Society's Gardens during the past week include a Barbary Ape (*Macacus inuus*), a Turtle Dove (*Turtur communis*), four Barbary Turtle Doves (*Turtur risorius*), four Barbary Partridges (*Caccabis petrosa*), a Crested Lark (*Alauda cristata*) from Morocco, presented by Mr. Alfred J. Gosling; a Caracal (*Felis caracal*), from South Africa, presented by Mr. J. E. Matcham; a Brown Capuchin (*Cebus fatuellus*) from Guiana, presented by Mr. T. A. Jenkins; a Common Buzzard (*Buteo vulgaris*) from Aden, presented by Captain R. Workman; a Lanner Falcon (*Falco lanarius*), captured at sea, presented by Mr. Arthur J. Elliott; a Hawks-billed Turtle (*Chelone imbricata*) from the East Indies, presented by Captain E. F. Tyacke; two Long-nosed Crocodiles (*Crocodilus cataphractes*) from West Africa, presented by Mr. J. Banks Elliott, three Rusa Deer (*Cervus hippelaphus*, ♂ ♀ ♀) from Mauritius, presented by Rear-Admiral Kennedy; two Somali Ostriches (*Struthio molybdophanes*) from Somaliland, purchased; four Plumed Ground Doves (*Geophaps plumifera*) from Australia, received in exchange.

OUR ASTRONOMICAL COLUMN.

THE SPECTRUM OF δ CEPHEI.—M. A. Belopolsky has taken a number of photographs of the spectrum of δ Cephei—a variable of short period—and determined from them the velocity of the star in the line of sight. The results obtained showed a periodic variation, and M. Belopolsky used them to find the elements of the star's orbit, in the manner described by Dr. Lehmann-Filhés in the *Astronomische Nachrichten*, No. 3242 (see NATURE, August 2, p. 327). He finds that the eccentricity of the orbit is 0·46; and the apparent semi-major axis 180,000 geographical miles (207,000 English miles). The period of the star is 5d. 9h. The maximum velocity of approach is about 2 8 statute miles per second, and of recession 3·2 miles per second. The system, as a whole, is therefore moving away from our own system. It is found that the light-minimum occurs one day before the time of periastron passage given by the computed elements of the orbit.

THE ROTATION OF VENUS.—For eight years M. Flammarion has carried on observations of the polar caps of Venus, and, in the current *Comptes-rendus*, he discusses the bearing of his results upon the question of the planet's period of rotation. It will be remembered that Schiaparelli concluded in 1890 that the rotation and revolution periods of Venus were of the same length, viz. 225 days; but later observations by Trouvelot and others have led many astronomers to doubt this interpretation, and to believe that the rotation period of the planet is not very different from that of the earth. M. Flammarion remarks that if it is conceded that the polar caps are really due to snow or ice, their very existence is against Schiaparelli's view. As the two caps are often visible at the same time, it appears that the axis of Venus is but slightly inclined to the orbit. M. Flammarion's observations of markings on the planet are not sufficient to determine the period of rotation, but they appear to indicate that it is not far removed from twenty-four hours.

THE LOWE OBSERVATORY.—A few particulars with regard to the new astronomical observatory, which has lately been erected in Southern California by Prof. T. S. C. Lowe, are given in Saturday's *Times*. The observatory is seven miles by rail north of Pasadena, and sixteen miles north-east of Los Angeles. Its altitude is about 3600 feet above the sea, and 2000 feet above the hill at the base of the mountains, which are very steep at this point. While the crest of the range rises high above the observatory and shelters it on the north, leaving, however, the North Star visible, the entire southern horizon is unobstructed, extending to the rim of a large segment of the Pacific Ocean, about 100 miles distant, on the south and west. Astronomically, it is nearly at the intersection of the 34th parallel of north latitude with the 118th meridian of longitude west of Greenwich. The new observatory is well equipped with the great 16-inch Clark reflector and other instruments which have done notable work in the Warner Observatory at Rochester under the directorship of Dr. Lewis Swift, who will now superintend the Lowe Observatory.

THE MEAN PARALLAX OF STARS.—In the *Astronomische Nachrichten*, No. 3258, Prof. Hugo Gyldén gives the results of his attempts to discover a formula connecting the parallax of a star with its magnitude and its apparent motion. The fifty-six stars which have had their parallaxes determined with a satisfactory degree of accuracy were arranged in groups according to their magnitude and according to their apparent motion. After a lengthy series of tentative formulæ, the observed values were connected within about ten per cent. by the following formula,

$$P = 0''\cdot204\, e^{-0\cdot2139 m\, \Psi_m}$$

where $\Psi_m = 2 - \left(\frac{1}{e}\right)^{\frac{m}{10}}$ m is the magnitude, and P the parallax of stars exhibiting no proper motion. For stars with proper motion a term p^1 has to be added to P, the value of which tends to 0"·48 as the magnitude, and the proper motion increases. So long ago as 1872, Prof. Gyldén showed that it is justifiable to deduce the distance of a group of stars from their apparent mean brightness in all cases where the probability of a certain intensity of illuminating power is a function of this intensity alone, without depending upon position in space. And since the photometric law has been proved to be at least approximately valid in this case, it may be concluded that the brightnesses of stars reduced to the same distance are the same, on an average, for all distances which can enter into our consideration. But the most important result of the present investigation is the determination of the mean parallax of first magnitude stars reduced to the zero of apparent motion. The value for this, which is 0"·204, may be considered as identical with Peters's value of 0"·209, especially when it is borne in mind that the latter value is not reduced to zero apparent motion.

THE INSTITUTION OF MECHANICAL ENGINEERS.

ON Wednesday and Thursday evenings of last week, October 24 and 25, a general meeting of the Institution of Mechanical Engineers was held at 25 Great George Street; the President, Prof. Alexander B. W. Kennedy, occupying the chair. The two following papers were read and discussed:

"The Manufacture of Standard Screws for Machine-made Watches," by Mr. Charles J. Hewitt, of Prescot.

"Drilling Machines for Cylindrical Boiler Shells," by Mr. Samuel Dixon, of Manchester.

Mr. Hewitt's paper was of an interesting nature. He is the works manager and chief mechanic of the Lancashire Watch Factory, an establishment recently started at Prescot for the manufacture of watches on a large scale in one works. The factory system of watch production has been, as is well known, carried to a very successful issue in the United States, where the Elgin and Waltham Watch Companies annually make large numbers of excellent time-pieces wholly by machinery. As, in all cases, where highly skilled hand labour, performing intricate operations, is superseded by mechanical appliances, the machines used are of a highly organised and costly nature. In the case of the minute parts required in watch-making, this feature is very strikingly emphasised. Perhaps some of our readers may remember the exquisite little machine tools exhibited by the Waltham Watch Company, at the Inventions Exhibition, in the year 1885. These were a revelation to most English watchmakers, accustomed to the small factories and perfectly rude appliances of the British industry, in which the highest skill of the operators, due to special training from earliest youth, compensated for the lack of ingenuity displayed in the construction of the tools used. In the case of watches, as with so many other mechanical productions, the brain capital expended in the employment of construction of machines bears fruitful interest in the shape of less skilled labour required in their use. The same thing may be observed throughout the whole range of mechanical industry. The file, the hammer, and chisel are the primitive tools of the engineer, requiring simple inventive power in their inception, but great skill in their use. The planing machine, by which the same end is obtained mechanically, of producing a flat surface, as was got originally by chipping and filing, required knowledge and skill for its production, but a comparatively small amount of those qualities for its operation. The same thing is true, even to a greater extent, in the case of the still more modern machine tool, the milling machine, which is often attended by boys, possessing no mechanical knowledge whatever, during its production of finished forms such as would have required a highly skilled workman in former days.

The beautiful machines referred to by the author in his paper, examples of which were shown at the meetings, carry the same principle many steps farther. As was remarked, the machine shown for making watch-screws may be said to stand in the same relation to ordinary engineers' machine tools as costly gems to common building stones.

Mr. Hewitt commenced his description by dwelling upon the difficulties experienced by watchmakers in old times, when there was no general standard for dimensions and pitch of screws, or form of thread. Such was necessarily the case with hand-work, but a machine can be depended upon to turn out many thousands of parts exactly similar, so that a screw could be put into a watch made years previously. The advantage, naturally, is most apparent in the case of repairs and renewals. The standard of screws adopted by the Lancashire Watch Company at their Prescot Works, is that recommended by the committee of the British Association, and described in the report of 1882. It is a V-thread of 47½ degrees, rounded top and bottom through $\frac{1}{6}$ of the height, and the pitch is directly related to the diameter of the formula $D = 6P^{\frac{6}{5}}$. In arranging the standard the first business was to make master taps, which were produced on a small screw-cutting lathe specially designed for the work, and having a corrected screw, accurate within very close limits. Taps being thus produced, screw-dies were made to the exact standard. When cut the thread requires hardening, and this causes some amount of distortion, which is corrected by grinding the threads with a soft steel lap charged with diamond dust, the operation being performed in the same lathe that cuts the thread. The die used is simply a tapped hole in the centre of a small thin disc of steel, it being an object to have as little metal as possible surrounding the hole, so as to reduce the distortion produced by hardening. Although the die is not split, the pressure exerted by the die-holder is sufficient to produce a slight modification in the diameter of the screw, and in this way the alteration caused by hardening is corrected. During the discussion this fact was questioned, but Mr. Hewitt says that the statement is absolutely correct. The machine itself is of an intricate design, as may be imagined when it is stated that perfect screws are turned out automatically from the plain rod or wire. There are four hollow spindles through which this wire is fed forward to the operating tools, which are four in number, and are carried on a revolving turret. There is also a further tool for making the slit in the screw-head for the turn-screw. It would be useless to attempt to describe the mechanism of this very ingenious lathe without the aid of elaborate drawings. Indeed, during the discussion several engineers, well skilled in mechanical appliances, confessed themselves unable to follow the train of mechanism, even with the aid of working drawings displayed on the walls of the theatre. It is enough to say that the machine will go on without any attention so long as the wire to form the screw lasts, when it stops of itself.

A short discussion followed the reading of the paper, but no fresh points were raised; the speakers, for the most part, contenting themselves with complimenting the author on the ingenuity of his design.

On the second evening of the meeting, Mr. Dixon's paper, on drilling machines for boiler shells, was read and discussed. The introduction of steel as a material for steam-boiler construction opened up a new era in that branch of industry. When iron plates only were used, a first-class boiler-shop possessed, as the chief part of its plant, simply a punching machine and a pair of rolls for bending the plates; the rest was done by handwork, and that of a highly skilled nature. Now that machinery has superseded the handicraftsman, rivetting is done by most costly and beautifully designed hydraulic apparatus, necessitating in its invention a knowledge of applied science of a high order. Flanging of the immense boiler-plates of the present day is also effected by heavy hydraulic presses. The rolls now used for bending plates have to be designed on true mechanical principles, whilst great advance has been made in drilling machinery. Thus both in the enormous boilers of our large steamships and in the diminutive mechanism of watches, we see the skilled handicraftsman being displaced by automatic machinery. It was soon found impossible to make steel boilers with the same plant that was used for the old type of iron boilers; the difference in the physical properties of the material alone demanded a change in treatment. The softer and less homogeneous iron enabled the rivet-holes to be punched, but it was found that this work done upon steel plates caused a deterioration of the metal; drilling, therefore, had to be substituted for punching. Iron plates were punched in the flat; but it was found that with steel when the holes were made in that way, they often would not go together accurately so as to take the rivets to the greatest advantage, the result being a weak joint. This did not matter so much when steam pressures were low, but with the greater demands made by the marine engineer in producing motive power economically, higher pressures had to be used, and there was no margin for loss in the line of rivetting. It therefore became customary to bend the plates and put them into shape to form the shell of the boiler before making the holes, which were then drilled in position, and were necessarily true. This procedure involved the use of special drilling machines, whilst economy demanded that several drills should work at once in one machine so as to save time and be under the care of only one attendant. The chief object of Mr. Dixon's paper was to describe the most recent of these machines. The drill spindles are carried on supports which bring them to the work, and are adjustable to the varying pitches and angles required. There is a cross-slide which can be raised or lowered for carrying the drills for the circular seams, and this is adjustable so as to suit the varying threads required. There are five drills for this purpose, whilst six more are arranged upon a vertical column upon the opposite side of the boiler shell for operating upon the butt seams. One of the chief difficulties in drilling holes in a built-up shell is the flexibility of the work, which causes it to give way and buckle when the pressure of the drills is brought upon it. So great has been this drawback that it has been found more advisable in many cases to use only one drill at a time, although there may have been four spindles on the machine. Mr. Dixon has overcome this objection in an ingenious manner by an internal support which gives great rigidity to the shell, and enables the larger number of drills to be brought into play at once without their accumulated pressure causing deflection. During the discussion an interesting point arose in connection with this feature. It was said that twist drills which, when properly ground, gave very clean holes and great accuracy of work, could not be used on boiler shells, as they so frequently broke in work. The author said this was perfectly true in ordinary cases, but it was due to the springing of the shell referred to. The statement is corroborated by the fact that twist drills can be advantageously employed on work firmly held on the drilling machine-table, whereas the older form of flat drill would have to be used where rigidity could not be obtained.

A NEW METHOD OF PREPARING PHOSPHORETTED HYDROGEN.

A NEW and extremely simple mode of preparing phosphoretted hydrogen is described by Prof. Retgers in the current *Zeitschrift für Anorganische Chemie*. After reviewing the usual mode of preparing the gas for demonstration purposes, by heating yellow phosphorus in an aqueous solution of potassium hydrate, and the other more rarely employed methods of preparation—such as by the interaction of calcium phosphide and hydrochloric acid, copper phosphide and potassium cyanide, and phosphonium iodide and water—the question of the direct combination of hydrogen and phosphorus is discussed. It appears that the currently accepted idea that ordinary molecular hydrogen does not combine with phosphorus is founded upon some old experiments of the French chemists Fourcroy and Vauquelin, who state that when phosphorus is melted in hydrogen gas, vapour of phosphorus becomes diffused in the hydrogen, and confers upon it the power of ignition in contact with oxygen without any combination between the phosphorus and hydrogen occurring. In view of the great readiness which, as Prof. Retgers has recently shown, warm hydrogen exhibits to unite with free arsenic, it was considered possible that the reason for the non-combination of hydrogen and melted phosphorus might be found in the low melting-point (44°) of the latter. Experiments were therefore made with red phosphorus, which, of course, is capable of being raised to a much higher temperature. When dry hydrogen is led through a glass tube containing red phosphorus, and afterwards through a wash-bottle containing water, practically pure hydrogen is found to escape. Immediately, however, a gas flame is brought under the part of the tube containing the phosphorus, combination occurs, and the gas issuing from the wash-bottle at once inflames in the air. The non-spontaneously inflammable gaseous hydride of phosphorus is also therefore accompanied by a smaller quantity of the spontaneously inflammable liquid hydride, and a sufficient quantity of the latter for demonstration may be isolated by leading the vapours through a U-tube immersed in a freezing mixture. Moreover, the solid hydride is likewise produced as a yellow deposit near the heated portion of the tube. Upon removing the flame from beneath the tube, the bubbles of escaping gas cease to take fire as they emerge into the air, and are found to consist of almost pure hydrogen. The production of phosphoretted hydrogen is consequently entirely dependent upon the elevation of the temperature considerably above the melting point of ordinary yellow phosphorus. The new mode of preparation is recommended by Prof. Retgers as being more convenient and elegant than the old-established method of boiling phosphorus in caustic potash, as forming an excellent example of the direct combination of two elements, and as furnishing ample demonstration of all three hydrides of phosphorus, the gaseous, liquid, and solid.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Rolleston Memorial Prize has been awarded to M. S. Pembrey, of Christ Church, and E. S. Goodrich, of Merton College, the papers sent in by these two candidates having been judged to be equal. Mr. Pembrey was placed in the first class in the Honour School of Natural Science in 1889, and is demonstrator in the Physiological Department. Mr. Goodrich is still an undergraduate, and is assistant to the Linacre Professor. At a meeting of the Junior Scientific Club, held on Friday, October 26, Mr. W. J. Waterhouse, of Christ Church, exhibited some telephone cables, and Mr. W. P. Pycraft exhibited some Natterjack toads. Papers were read by Mr. W. Garstang, of Lincoln College, on some modifications of the Tunicate pharynx induced by the violent ejection of water, and by Mr. C. T. Blanshard, of Queen's College, on the genesis of the elements.

Sir Henry W. Acland, K.C.B., has announced his resignation of the Regius Professor of Medicine, the resignation to take effect at the end of the present year. Sir Henry is now in his eightieth year, and has long been a leading figure in scientific and medical matters in the University. His resignation will sever the link of many old associations. He has consistently and bravely supported the cause of science in Oxford, and that, too, at a time when scientific studies were regarded in anything but a favourable light by the rest of the University. It was largely due to his influence and energy that the University Museum was built, and he has never failed to support any movements for its further extension and for the improvement of the teaching which is carried on there. One of his latest efforts secured the building of the new Department of Human Anatomy, and he has had the satisfaction of seeing the medical school for which he worked so hard rise from almost nothingness into considerable dimensions, with every prospect of steady and healthy increase. He will carry with him on his retirement the affection and good wishes of all sections of the University.

SCIENTIFIC SERIALS.

IN the *Nuovo Giornale Botanico Italiano* for October, Sigg. G. Del Guercio and E. Baroni describe the disease of Italian vines caused by a Schizomycete, and known as *gommosi bacillare* or *gelivure*.—Sig. C. Massalonga describes a large number of abnormal growths in different plants.—All the other papers concern the local Italian flora.

IN the *Journal of Botany* for August, September, and October, Mr. F. J. Hanbury adds seven more to the interminable list of new species of *Hieracium*.—Rev. E. S. Marshall describes and figures an apparently new species of *Cochlearia*, *C. micacea*, from Ben Lawers.—Messrs. J. G. and E. G. Baker discuss the botany of an interesting corner of Westmoreland, High-cup Nick.—The Ericaceæ and the Asclepiadeæ of South Africa are treated of, respectively, by Mr. H. Bolus and Mr. R. Schlechter.—Students of the local distribution of plants in Great Britain will find other papers to interest them.

Symons's Monthly Meteorological Magazine, October.—Protection from lightning, by A. McAdie. This is a summary of one of the Circulars of Information issued by the Weather Bureau, Washington. In addition to a number of rules for erecting lightning rods, the pamphlet contains statistical tables of injury to life and property by lightning in the United States. Full recognition is given by the author of the Report of the Lightning Rod Conference published in 1882, and of the experiments made by Prof. Oliver Lodge.—The recent drought in the Midlands, by the Rev. G. T. Ryves. During 26 days ending September 21, only 0·06 inch of rain fell at Tean Vicarage. Mr. Symons shows that at Barkby, Leicestershire, 1·10 inch of rain fell. The same record shows that the first nine months of

1894 have been dry, but not nearly so dry as in some previous years.—Enormous hailstones, by G. J. Symons. This contains some cuttings from various papers of a severe thunderstorm which occurred over a large part of the continent on August 26 and 27 last. At Beaucourt hailstones are said to have been picked up weighing nearly two pounds; at many places they weighed seven ounces and upwards, and many birds and some sheep were killed.—Climatological table for the British Empire for the year 1893, by G. J. Symons. The table contains data referring to temperature, rainfall, &c., at eighteen places. The highest temperature in the shade was 108° at Adelaide, on February 2, and the lowest − 48° at Winnipeg. on February 1. The highest temperature in the sun was 171° at Trinidad, which also had the greatest rainfall, viz. 92·5 inches; the least fall was in London, 19·8 inches.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 22.—M. Lœwy in the chair.—Experimental verifications of the theory of weirs, with liquid sheets submerged below or adherent, relative to the delivery and the contraction in the lower part of the liquid sheet, by M. J. Boussinesq.—M. A. Trillat claims priority in regard to processes of disinfection by formaldehyde.—On the rotation poles of Venus, by M. C. Flammarion (see p. 21). Variations of the level of water in a basin communicating with a tidal port, by M. A. de Saint-Germain. A mathematical paper. —Force acting at the surface of separation of two dielectrics, by M. H. Pellat. In the general case, the force is normal to the surface of separation and in the sense that the specific inductive capacity diminishes. Its value per unit of surface is given by the formula

$$f = \frac{K_1\phi_1^2 \cos 2a_1}{8\pi} - \frac{K_2\phi_2^2 \cos 2a_2}{8\pi},$$

a_1 and a_2 being the angles between the normal and the direction of the field, ϕ_1 and ϕ_2 the intensities of the field, on either side of the surface of separation.—Experimental researches on the freezing-point with different mixtures of alcohol and water, by M. Raoul Pictet. A table of the temperatures of crystallisation of definite mixtures is given, and the results are plotted in curves discussed in the paper.—A study of the combinations of hydrogen fluoride with water, by M. R. Metzner. The author has succeeded in obtaining only one hydrate possessing definite properties. It has the composition $HF.H_2O$ and contains 52·3 per cent of HF. The crystals of this composition melt at − 35° C.; they fume in the air, and have a specific gravity greater than 1·15. They are very soluble in the cold concentrated acid.—Researches on the mercuric sulphates, by M. Raoul Varet. The thermal data for the normal sulphate and for the basic salt $HgSO_4 . 2HgO$ are given in detail. Whereas sulphuric acid completely displaces HCN from its combination with potassium liberating + 25·4 Cal., hydrocyanic acid, even in dilute solution, replaces sulphuric acid in $HgSO_4$ with disengagement of + 23·5 Cal. Similarly hydrochloric acid displaces sulphuric acid in $HgSO_4$.—Antimony vermilion is not an oxysulphide, by M. H. Baubigny. Analysis of the colouring matter of antimony vermilion, precipitated by sodium thiosulphate, shows that it is simply a form of Sb_2S_3.—Bismuth nitrosalicylates, by M. H. Causse.—Salivary glands of the Apinæ (*Apis mellifica* ♂ and ♀), by M. Bordas. On an undescribed caterpillar ravaging the leaves and fruits of the fig-tree, in the arrondissement of Puget-Théniers, by M. Decaux. —On the mechanism of vegetable respiration, by M. L. Maquenne. The author shows that the ratio of CO_2 produced to O absorbed is sensibly altered by momentarily subjecting leaves to a vacuum, and the respiration is at the same time rendered more active. The conclusion is given: The respiration of plants appears to be the result of the slow combustion of a very oxidisable principle, which the living cell constantly secretes, shaded from the light, and which may accumulate when there is insufficient oxygen in the surrounding atmosphere.—The station of Schweizersbild, by M. Nüesch.—Three geological sections in French Congo, by M. Maurice Barrat.—Late geological researches in the Altai, by M. Vénukoff.—Rotation movements observed in an aerostatic ascension, by M. Vénukoff.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, NOVEMBER 1.

LINNEAN SOCIETY, at 8.—Contributions to the Knowledge of Monocotyledonous Saprophytes: Percy Groom.—On an Error in the Descriptions of the Effect of a Centrifugal Force upon Growth: Rev. G. Henslow.—On Mediterranean and New Zealand Retepora, and a Fenestrate Bryozoan: A. W. Waters.

ANCIENT METEOROLOGY.

Theophrastus of Eresus, on Winds and on Weather Signs. Translated, with an Introduction, and an Appendix, by Jas. G. Wood, M.A., LL.B., F.G.S., and edited by G. J. Symons, F.R.S. (London: Stanford, 1894.)

THIS book owes its appearance in an English dress to the action of Mr. G. J. Symons, who believed its contents to be of such value and interest, that he offered to defray the expenses of publication provided a competent authority would prepare a translation of this neglected author. An able and willing translator was found in Mr. J. G. Wood, sometime Fellow of Emmanuel College, Cambridge, and we are thus put in easy possession of the thoughts and the science of Theophrastus, or it may be the wisdom of Aristotle, filtered through the mind of his favourite pupil. It need scarcely be said that the book possesses a greater interest for the archæologist than for the pupil of modern science, whose habit of thought is so different from that of the old Greek author, that he will have a difficulty in attempting to follow him.

A main object that Mr. Symons had in his generous proposal was to offer the means for the study of the gradual growth of our knowledge of meteorology, as exhibited in the literature of past ages. He has, therefore, begun at the fountain-head, or as near as was possible or desirable. Mr. Wood seems to have been animated by a somewhat similar ambition. He is afraid that in the study of meteorology, as at present existing, the student may be tempted to forget "the far-off and small but necessary beginnings which have conduced to such an end." In this sentence there are several words to which one might, if in a captious mood, take exception. For instance, can meteorology, in any sense, be said to have its beginning in the school of Aristotle or Theophrastus? Certainly not in the same sense in which astronomy could be said to have its rise in the work of Hipparchus or Ptolemy, for whatever errors may have vitiated their reasoning and impaired their results, they were in an advanced position compared with those who taught or who studied meteorology before they had an adequate conception of the existence of an atmosphere. Again, is it necessary that science should have its origin in error? Hasty generalisations, imperfect judgment from insufficient facts, one must expect, but there will always be a central thought which successive students will develop and render fruitful, and in Theophrastus this germ seems to be absolutely wanting. It is rare, if not impossible, to find any paragraph which is scientifically correct, or in which any train of reasoning is sound, so that we fail to see how the efforts of Theophrastus and his predecessor have in any way conduced to the position, imperfect as it is, in which meteorology now stands. Mr. Symons has told us that he hoped to capture some new thought from the study of this author. We venture to say he has been disappointed, for whatever interest the book may have for the curious and the literary student, it has little or none for the scientific.

We have in this little book two treatises, or (as Mr. Wood says we should now call them) "papers," of Therophrastus, one on "The Winds," the other on "Weather Signs." Both are marked by traces of haste in their original compilation, and assume a better acquaintance with the writings of Aristotle than most people at the present day possess. But even with this knowledge, the author is difficult enough to follow; accordingly Mr. Wood in his introduction has endeavoured to give the English reader a notion of Aristotle's views on Wind. This it will be admitted is no easy task, within the small limits permitted to the translator; and if the explanation is not everywhere so clear nor so full as could be wished, the fault lies not with Mr. Wood, but in the intricacy of the subject, and in the difficulty the reader finds in endeavouring to follow the subtleties of Aristotle, and of accommodating modern thought and knowledge to the ancient methods of expression. It is a treat, after wandering through the mazes of "dry sublimation" and "moist sublimation," to come to Mr. Wood's summing up of the whole matter, in which he endeavours to concentrate his intimate knowledge of this subject, as it presented itself to the Greek mind. "The winds"—and Mr. Wood draws a necessary and picturesque distinction between πνοή, ἄνεμος, and πνεῦμα—"are separate and distinct entities, flowing in definite courses, and not mere movements of the same air hither and thither: that to produce wind matter has to be formed, and the more matter the greater the wind: and this matter is derived from the earth, and is distinct from vapour."

With these misconceptions influencing the Greek mind, and giving rise to infinite confusion, it would be tedious to point out all the errors into which Theophrastus fell. He was apparently not the kind of man to substitute patient and exact observation for the assertion and teaching of authority, or we might have had to hail him as the founder of exact meteorology. One example will suffice to illustrate his success as an original investigator. We select the subject of annual or periodic winds (ἐτήσιαι), which Mr. Wood renders not very happily by "monsoons." The origin of these winds our author teaches us is to be traced in the melting of the snow. As the sun breaks up the frost, it sets the air in motion, giving rise to the "monsoons," and inasmuch as the thaw does not proceed with perfect regularity, so the wind varies in constancy. At night, when the action of the sun is less powerful and the thaw does not proceed, the wind ceases to blow, but under exceptional circumstances the thaw may be so rapid that the wind is perceived at night. Did none of his pupils seek to verify these statements?

The attempts at weather forecasting are naturally not more happy than those dealing with meteorological science, as now generally understood, but possibly quite as accurate as many of the predictions quoted in our days, having for their object the determination of the weather for a considerable period in advance. Certainly they rest on a foundation quite as sound, and doubtless assume an equal ignorance in the public, that circulate them from mouth to mouth, or it may be from newspaper to newspaper. "Whatever," says Theophrastus, "be the condition of the air at the setting of the Pleiades, such it continues for the most part, until the winter solstice." This would cover practically nine months of the year, if by the setting of the Pleiades is meant the setting with the sun. The moon, too, is either the cause of a change or the prognostication of it. "The change takes place for the most part on the fourth day, and if not then on the first quarter, and if not then at the full." A weather prophet of to-day would be discredited if he hedged in this way. A clear crisp statement is now necessary to secure credence, and attach disciples to the school of the modern weather prophet. As one turns over the pages that give the signs of fair or foul weather, signs all more or less puerile, one is reminded of the saying that Plato has preserved for us, Ἕλληνες ἀεὶ παῖδές ἐστε.

We can have no hesitation in asserting that the appendix is the most valuable part of the book. Herein, Mr. Wood has given an excellent account of the gradual changes introduced in the nomenclature and in the subdivision of the winds from the time of Homer and Hesiod, through the Middle Ages, down to the present time. Such an account is not only of great assistance to the correct apprehension of old authors, but gives a great deal of information on the introduction of fresh terms in the description of the winds. Mr. Wood seems distressed as to the exact localisation of a wind that is defined by reference to the azimuth of the sun, at rising or setting at the summer and winter solstice. Of course the azimuth varies with the latitude of the place of observation, but Aristotle, writing for Greeks, described positions as they were seen in Greece. Mr. Wood might as well have taken into account the effect of refraction at the horizon, or the alteration in the obliquity of the ecliptic. In these days, we rarely attempt to determine the direction of the wind within 20°, and it is scarcely likely that greater accuracy was attempted in Greece. But whether Aristotle spoke of the equator or Athens, the whole difference is only about 6°, so that the question of accuracy hardly enters. We congratulate Mr. Wood upon the amount of well-digested information he has been able to give in this chapter. W. E. P.

TWO BOOKS ON AMERICAN ANTIQUITIES.

Travels amongst American Indians, their Ancient Earthworks and Temples; including a Journey in Guatemala, Mexico, and Yucatan, and a visit to the Ruins of Patinamit, Utatlan, Palenque, and Uxmal. By Vice-Admiral Lindesay Brine. (London: Sampson Low, 1894.)

Journal of the Academy of Natural Sciences of Philadelphia. Second series, vol. x. part I. (Philadelphia: Academy of Natural Sciences, 1894.)

ADMIRAL BRINE'S pleasantly written book is the record of a journey made through the United States, Guatemala, and Yucatan in the years 1869–70. It is to be regretted that his notes were not published at once on his return home, as in those days Guatemala and Yucatan were still almost unknown lands, and since that date half a dozen books—few of them, it must be admitted, of great value—have made the country more familiar to us.

The particular object of Admiral Brine's journey was the examination of the earthworks and temples of the American Indians, and the first portion of the book is devoted to the red man and his works. Several months were occupied in examining the mounds and earthworks in Ohio.

On the difficult question of age, the author favours the view that the circular and octagon enclosures are of comparatively late date.

"But the figure which would have been absolutely impracticable to construct without proper surveying appliances for making accurate measurements, and fixing the true angles, is that of the octagon. Even under the most favourable circumstances, with the help of suitable instruments, it would have required much skill and calculation to trace a true octagon, whose embankments contained within them an area exceeding forty acres. It is difficult to suppose that an accurately designed work of this shape and magnitude could have been planned by Indians, or that the construction of a figure so essentially scientific and unusual, could have been originated by them. It is therefore possible to conclude that the geometrical earthworks in Ohio may have been raised by native tribes, acting under the direction of European surveyors, or men who had received a mathematical education."

Concerning the Indian tribes who actually did the work of raising the embankments, the author adds in a note that—

"Nothing has been found amongst the ornaments or weapons that were placed in their burial mounds, which supports the hypothesis that they were different in race or intelligence from the tribes that surround them."

From San Francisco, Admiral Brine sailed down the Pacific Coast to Guatemala. He tells a story of Carrera, that remarkable Indian of pure blood, who was for so long the President of the Republic, and of whom mention is often made in "Stephens' Incidents of Travel in Central America."

"Colonel Garcia told us that Carrera always had on his writing-table a toy representing Louis Philippe with his hat in his hand. This toy had a rounded base, and was so weighted that, when it was touched, it rolled backwards and forwards, and would thus represent Louis Philippe constantly bowing, hat in hand. Carrera when engaged in official work would frequently make the toy move, and then would say to those who stood near him, 'It seems in that way, by too much bowing, that Louis Philippe lost his throne. I shall take care that I do not make the same mistake.'"

A journey in Guatemala in 1870 was by no means as free from risk as it is at the present day, "pronunciamientos" and Indian risings were not of uncommon occurrence, and Admiral Brine was fortunate in escaping any serious danger; but he, no doubt, principally owed his immunity from trouble to tact and good temper in his dealings with the Indians. He was usually indebted to the "padres" for hospitality on the road, and learnt from the priests themselves how independent the Indians had become in matters of religion.

"'The Indians come and go as they please,' said Father Hernandez, 'light their own candles, hold their own services before the altar, and frequently take one of the saints out of the church, and carry it away to some hut, where for several days they will perform musical ceremonies before it, and then the saint will be brought back to its proper altar'—and again, 'they come from afar to make offerings of blossoms and leaves, light candles before the altars of those saints they wish to honour, and then silently return to their huts.'"

There can be little doubt that in pre-Christian times they were accustomed to an elaborate ritual, and it was partly for this reason that they took so readily to the ceremonies of the Roman Church, but they never quite abandoned their old beliefs. The twenty-four years that have elapsed since Admiral Brine's journey have not made much difference in this respect; and little rough altars may any day be found on the tops of abandoned temple mounds with the scent of incense still hanging about them.

Admiral Brine camped for a few days in the ruined temples at Palenque, and then travelled northwards to Yucatan and visited the ruins of Uxmal. The last two chapters give an interesting summary of the author's notes and the conclusions to which he has come. With these conclusions it is not always possible to agree; but that is not much to be wondered at, when dealing with a subject which is so closely enveloped in mystery as the civilisation and migrations of the races of America.

Happily we can feel assured that a distinct advance in our knowledge of the subject is being made, and that there is a fair prospect that, within the next few years, some at least of the mystery will be rolled away.

A good example of the very careful work which is being done by numerous scientific societies in America, in collecting and examining prehistoric remains, can be seen in Mr. Clarence B. Moore's account of his excavations in the sand mounds of the St. John's River in Florida, and Mr. W. H. Holmes's notes on the pottery from these mounds, which was submitted to him for examination, both published in the *Journal* of the Philadelphia Academy of Sciences.

The sand burial mounds occur frequently in the neighbourhood of large shell deposits. They are usually stratified, the layers consisting of different coloured sand, with sometimes a slight admixture of shell, and the human bones and other objects are most frequently found in a layer of sand of a pinkish colour, due to the presence of powdered hematite.

It is not unusual to find in Indian burial mounds pottery which has been purposely broken before burial, as though in observance of some ceremonial rite, but in these sand mounds Mr. Moore found mortuary pottery in which the breakage or perforation had been made before the pottery was fired.

With some of the surface and intrusive burials were associated iron and brass objects, showing them to have been post-Columbian; but nothing indicating contact with Europeans was found associated with the deeper interments, and many of the mounds were entirely free from evidence of contact with white men.

At Thursby Mound a number of very curious rough pottery figures were found, representing squirrels, turkeys, fish, turtles, &c., as well as some vegetal forms, which are extremely rare in the normal art of the United States. The illustrations which accompany these notes are numerous and excellent.

As we hear that Mr. W. H. Holmes, whose admirable work is so well known, is leaving the Bureau of Ethnology at Washington, in order to take charge of the new and liberally endowed museum at Chicago, which is the outcome of the great World's Fair, we may look for steady and increasing contributions to our knowledge of the Indian races and their arts, which will not be limited to the result of investigations in the territory of the United States, but will include the whole American continent.

The Peabody Institute of Massachusetts (principally owing to the liberal support afforded it by Mr. C. Bowditch, of Boston) has been able to set a good example in commencing systematic work on the central civilisations, by the investigations now being carried on at the ruins of Copan, the site of which has been acquired on lease from the Government of Honduras for a period of ten years. The Peabody Museum at Cambridge, with its fine collections of pottery, original sculpture and casts, is fast becoming a centre for the study of American antiquities.

WATTS' DICTIONARY OF CHEMISTRY.

Watts' Dictionary of Chemistry. Revised and entirely re-written. By M. M. Pattison Muir, M.A., and H. Forster Morley, M.A., D.Sc. Assisted by eminent contributors. Vol. IV. With Addenda. 8vo. Pp. 922. (London and New York: Longmans, Green, and Co., 1894.)

THE completion of the grand work before us renders it possible to form a fair estimate of its features and its general character. No candid reader can fail to appreciate the industry displayed by the editors and contributors, in bringing together and sifting out the vast mass of existing matter, in a science which is experiencing so rapid a growth. Perhaps a greater difficulty has been encountered in compressing within reasonable limits the facts which must claim insertion. This end has been reached by a style laudably laconic, but at the same time free from obscurity, and by an ingenious system of abbreviations, the editors—or we might better say the authors, since the entire work has been re-written—have confined themselves to the pure science, leaving its thousand and one applications in manufactures, metallurgy, and agriculture, to be dealt with in the "Dictionary of Applied Chemistry," issued by the same publishers. Without this limitation, the cost of producing the work would have been simply prohibitive.

Many of the articles included in this volume are, in their value and extent, almost worthy to rank as independent works. As instances we may mention the section on the Proteids; that on the Ptomaines—which might have been a little more extensive—the article on Phosphorus; and, above all, that on the Physical Methods used in Chemistry. This article, which extends to 100 pages, treats separately of methods based on capillarity, of crystallographic methods, of dialysis and diffusion, of dynamical methods, of electrical methods, of procedures based on the freezing-points of solutions, of optical methods, of methods based on osmotic pressure, of photographic methods, of methods turning on the specific heats of solids, of thermal methods, of those based on the vapour-pressures of solutions, of the viscosity of liquids, and of methods based on volume-changes.

The chapter on electrical methods is supplied by Prof. Dr. Ostwald, of the University of Leipzig. The author gives an account of the rise of electro-chemistry and of its development by Berzelius and Hisinger, and of its dominance down to 1840. It is remarked that, after his first investigations, Berzelius did not undertake any experimental work on the action of electricity upon chemical compounds. After 1840 this theory was found incapable of explaining facts which were being brought to light in the region of organic chemistry, whilst its physical foundations were shaken by the researches of Faraday. More recently, Hittorf, Arrhenius, Helmholtz and others have founded a new electro-chemical theory. Mention is made of the discussion—not yet decided—as to the origin of the current in the pile. The conception of ions as the material conveyance of the current has been gradually introduced since the researches of Clausius, and is taken into account in our views of decomposition. Not less interesting is the account of optical methods. The first part, from the pen of Mr. G. Gladstone, discusses refraction and dispersion; the second, on spectroscopic methods, is contributed by Prof. W. N. Hartley, F.R.S.; and the third part, on the rotation of the plane of polarisation of light, is by Prof. Pattison Muir. In the part treating of the spectroscopic methods we find studies of the infra-red and ultra-violet absorption spectra, with notices of the researches of V. Schumann, Waterhouse, Crookes and Gladstone. In connection with the absorption spectra —a subject by no means fully explored—we have a notice of Witt's views on the cause of colour in organic compounds.

Among the elements admitted or supposed, we find in this volume, notices of phosphorus, platinum, potassium, rhodium, rubidium, ruthenium, samarium, scandium, selenium, silicon, silver, sodium, strontium, sulphur, tantalum, tellurium, terbium, thallium, thorium, tin, titanium, tungsten, uranium, vanadium, yttrium, ytterbium, zinc and zirconium, with compounds or derivatives.

The authors and contributors are noticeable for a sobriety of statement; they do not indulge in premature conclusions and in speculations for which evidence is lacking.

As regards the elements, the Mendelejeff classification is adhered to, and in the accounts of their preparation the recent results of Moissan have not been overlooked.

The addenda comprise facts in mineral chemistry which have been observed since the appearance of Vols. I., II., and III. and the printing off the final proofs of the present volume. The addenda include nothing on organic chemistry; since to have noticed the recent discoveries in that department would, in the opinion of Mr. Pattison Muir, have required the addition of many hundred pages.

On comparing the present work with former dictionaries of chemistry, whether in English or in any other language, its superiority will appear beyond all question. It will be the obvious duty of all universities, colleges, &c., at once to add this new edition of "Watts" to their libraries.

DISEASES OF TREES.

Text-Book of the Diseases of Trees. By Prof. R. Hartig, of Munich University. Translated by W. Somerville, Professor of Agriculture and Forestry, Durham College of Science, Newcastle. Revised and edited by Prof. H. Marshall Ward, F.R.S. (London and New York: Macmillan and Co., 1894.)

"DER Lehrbuch der Baumkrankheiten von R. Hartig" has now appeared in English with all the admirable illustrative plates of the second edition, except the coloured plates at the end of the book, which represent spruce and oak wood decomposing under the influence of different fungi, and are therefore somewhat exterior to the proposed scope of the work, "the diseases of trees." The original, as Marshall Ward states in the preface to the present version, owes its great charm "to the simple method of exposition of the facts and principles conveyed, as well as to the astounding richness of the information it contains. This is unquestionably owing to Hartig's prominence as the leading investigator and authority on the fungoid diseases of forest trees."

The great superiority of Hartig's work in this subject has been acknowledged in France, by the publication there, in 1891, of a French translation by Profs. Gerschel and Henry, of the Nancy Forest School, which was entirely revised by the author.

Prof. Somerville, the translator of the present English edition, has followed a complete course of forestry at a German forest school, and has been for some time engaged in forestry instruction at Edinburgh and Newcastle. He has already written a valuable little book on the structure of European timbers. The translation of Hartig's book follows the original closely, and is smooth and free from Germanisms.

The editor, Prof. H. Marshall Ward, whose qualifications for the work need no comment, has written an excellent preface, besides revising the translation and supplying short foot-notes in explanation of all scientific terms, which might puzzle readers who have not studied vegetable physiology very deeply, and in a few cases giving his own opinion where he does not coincide with the authors.

In the preface, the bold but thoroughly justifiable statement is made that students of agricultural chemistry, or of the physics and chemistry of soils, must thoroughly master the facts of the structure and essential phenomena of life by experimental investigation, and that the chemistry of the soil taken alone is of less practical importance. The fact is, that although the want of sufficient suitable chemicals in a soil may render certain tree-growth stunted and unproductive, yet the physical nature of the soil, *i.e.* its degree of division and hygroscopicity, and the climate of the locality, are more important than the former to ensure a healthy and vigorous tree-growth; whilst a good coating of decomposing dead leaves will render a soil, which is chemically and physically poor, capable of producing a fair crop of timber. The influence of earthworms on soils has been dealt with by Darwin, whilst that of bacteria and other low organisms in decomposing organic débris to form humus, and otherwise assisting in the nutrition of plants, has yet to be dealt with in a special treatise. Considering the exhaustive and expensive investigations which are carried out in the research of animal pathology, a large expenditure by the State on the influence of bacteria on soil and water would be justifiable, and would lead to highly important improvements in agriculture and gardening.

The editor meets possible objections from botanical critics to Hartig's classification of fungi, by remarking that it is not fungi which are being studied here, but their action on trees, and that students may obtain a thorough knowledge of fungi elsewhere; he refers the forester who may be anxious to know the remedies against disease to special works,[1] although Hartig has given many practical hints as to treatment in certain cases.

The book's great value lies in the way it teaches students how to investigate disease, and a wide field is still open to discovery in this respect.

The author's introduction chiefly deals with the causes of disease and the procedure for investigating them; and it is reassuring to read that the transmission by inheritance of disease is unknown in the vegetable kingdom, and that we may use without hesitation the seed of plants suffering from any conceivable disease, and that with them the law of inheritance is only involved in the case of marked peculiarities, such as twisted fibre, dwarfed habit, and other undesirable peculiarities. Superior individual growth, however, is recognisable in the size of the fruit, and large acorns produce vigorous oak saplings.

As regards the distribution of matter in the work, the first forty pages after the introduction deal with diseases caused by plants other than fungi. Hartig states that he has not noticed any appreciable damage done to forest plants by *Cuscuteæ* or dodders, but Hess states that osier willows are greatly damaged by *Cuscuta Gronovii*, Willd., an American species which has established itself in Germany. The places where the *haustoria*, or sucker-like roots of the parasite, pierce the cortex of the plants, are rendered brittle, and the osiers so attacked become useless for basket-making. The only remedy appears to be to cut down the affected shoots in June and July, when the dodder blossoms, and burn them. Bacteria which cause such terrible diseases in animals rarely harm plants, owing to the closed nature of their tissue elements as compared with the anastomosing veins and lengthy digestive apparatus of animals.

The main portion of the book—pages 40–224—deals with damage done by fungi; and after a general description of their mode of life, a very clear account is given of the life-history of each destructive fungus, and of its effects on its host. Fortunately, whilst several of these species may destroy a few hundred trees here and there, the only fungus which can be compared for its ravages on whole woods with certain destructive forest insects is *Peziza Willkommii*, which causes the widespread larch disease, and has rendered the cultivation of larch almost impossible in certain districts in Great Britain and the north of Germany, though it is said not yet to have occurred in Ireland. The best preventive measure is to plant larch only on suitable soils and in open airy situations, and to mix it with other trees, and especially with beech.

[1] For instance, a translation of Hess's "Forest Protection" is now in the press, and deals with these questions in detail.

Besides dealing with fungi which infest living trees, there is a most interesting account of those which attack timber, and thoroughly practical suggestions are given for dealing with dry-rot caused by *Merulius lacrimans*.

Section ii. (pages 226–269) deals with wounds, and the mode nature adopts for healing them, and also with the dangers they afford by the admission of the spores of fungi to the interior of a tree. It is pointed out how branches should be pruned or shortened so as to avoid, as much as possible, the chances of future decay. Hartig states that he has never known an instance of coal-tar, when used for dressing wounds in trees, having proved hurtful to them, although some foresters have asserted the contrary.

Section iii. (pages 270–281) deals with diseases due to certain conditions of soil, the chief predisposing factor being the want of free circulation of air in the soil, which may cause root-rot in conifers, though, according to Hartig, never in broad-leaved species. This latter statement may not, however, be quite correct, as Spanish chestnut appears sometimes to suffer from root-rot, owing to this cause.

Section iv. (pages 281–304) deals with diseases caused by atmospheric influences, frost, insolation, want of light, hail, fire, coal-smoke, and lightning, and the book terminates with a classified list of diseases arranged according to the species of tree attacked, and the respective organs which suffer.

W. R. FISHER.

OUR BOOK SHELF.

Le Centre de l'Afrique. Autour du Tchad. Par P. Brunache. (Paris: Felix Alcan, 1894.)

THIS record of travel in a previously unknown region of north tropical Africa is published as volume 79 of *Bibliothèque Scientifique Internationale*, although there is nothing scientific about it, and the standpoint of the author, so far from being international, is exclusively and almost obtrusively French. The words "Autour du Tchad," which are repeated as the running title of the book, are entirely misleading, for the writer never came into the vicinity of Lake Chad at all, but passed more than 200 miles to the south of it. These are all the adverse criticisms we have to offer. For the rest, the book is lively reading, and has the merits of brevity and point. M. Brunache went out in 1891, as second in command to M. Dybowski, in an expedition for the relief of M. Paul Crampel, who had set out a year before, with small resources, from French Congo, to try to reach Lake Chad. Landing at Loango, the Dybowski expedition went to Brazzaville, on the Congo, and thence up the Mobangi and through a blank area of the map, peopled by Dakoas and N'Gapus, across the watershed between the Congo and Shari systems to nearly 8° N. The place of Crampel's murder was found, and a good deal of punitive fighting was carried on with the Mohammedan negroes; but here, at Crampel Peak, Dybowski found that it was impossible to go farther, and the expedition returned to the French outposts on the Mobangi. M. Brunache is careful to show how much better qualified he was for the command than the appointed leader, of whose wishes he seems not to have been too considerate. On his way to the coast our author met the expedition of

M. Maistre, to which he transferred himself, and again crossed the Congo-Shari watershed, made friends of many of the native tribes, obtained treaties in the usual way, and, pushing onwards, in spite of considerable hardships, descended one of the tributaries of the Shari, struck westwards to the Benue, and so returned by the Niger. The expeditions, which were two of the most important of the last few years, did much valuable work in geography and natural history; indeed, M. Brunache insinuates that Dybowski was too much devoted to collecting specimens to make an ideal commander.

The book contains many interesting but unsystematic notes on a number of tribes which were visited for the first time by Europeans. Except the Bonjios on the lower Mobangi, and the Mohammedanised natives of the Sudan, they were all cannibals, eating their enemies killed in battle, and occasionally their slaves. Amongst all the tribes, women were well treated and consulted on affairs of importance. The costume and habits of the Saras, a particularly tall tribe, who inhabit the Shari basin between 8° and 9° N., are described, we believe, for the first time, and with such fulness and tact as only a Frenchman can employ. In their country the surveys of the expedition touched those of Nachtigal, who had penetrated so far southward across the Sahara, and thus completed the chain of modern European itineraries in West Africa from the Mediterranean to the Cape of Good Hope.

A number of reproductions of sketches exhibit types of the natives encountered, and specimens of their art and manufactures.

Helical Gears. By a Foreman Pattern Maker. (London: Whittaker and Co., 1893.)

THIS little book belongs to "The Specialists' Series"; it is entirely of a practical nature, and deals with a subject little understood by engineers who do not happen to be machine-tool makers. As there is probably no other text-book on this subject, the work will fill a useful purpose. The author observes that a large proportion of so-called helical gears are incorrectly made, and are therefore far worse than common gears. With this observation we certainly heartily agree. Cases are known where an otherwise good machine has been spoiled by the use of badly designed helical gearing.

The arrangement of the information is good. Illustrations and diagrams are freely used, so that what would otherwise be difficult to understand becomes clear and apparent. Patterns are clearly dealt with, and their manufacture fully described. It is here the hand of the practical man becomes evident. Many hints are given, and instructions formulated, which flavour strongly of the "works." The author does not pretend to deal with the purely theoretical side of his subject, excepting in so far as the fundamental relationships of the helical gears to the true screw or helix is concerned. Beyond this the book is entirely of a practical character, being eminently fitted to fulfil the requirements of the drawing-office and the works. N. J. L.

The Nests and Eggs of Non-Indigenous British Birds. By Charles Dixon. Pp. 360. (London: Chapman and Hall, 1894.)

"THE present work," remarks Mr. Dixon in his preface, "forms the companion volume to 'The Nests and Eggs of British Birds,' and renders the subject of British Oology complete, so far as our knowledge now extends. It deals exclusively with the nidification of the birds that do not breed in the British Archipelago, but visit our islands regularly in winter, pass our coasts on passage, or pay them their more or less irregular visits as wanderers from their normal areas of disposal." Nearly two hundred species are described as belonging to this class. For each bird, information is given as to the breeding area, breeding habits, range of egg colouration and measurement, and the diagnostic characters of the eggs. In an appendix, the author states his reasons for believing that the nests and eggs of the following species are at present unknown to science:—Rustic bunting, Pallas's grey shrike, Siberian ground thrush, needle-tailed swift, solitary sandpiper, Siberian pectoral sandpiper, curlew sandpiper, knot, Ross's gull, great shearwater, collared petrel, capped petrel, Cape petrel, and white-billed diver. A list of forty species, individuals of which have been said to occur within the limits of the British Isles, but which Mr. Dixon regards as doubtful British species, is also appended to the volume. It remains for the scientific naturalist to collect some definite information on the species enumerated in these lists.

Commercial Geography. By E. C. K. Gonner, M.A. Pp. 200. (London: Macmillan and Co., 1894.)

COMMERCIAL geography, dealing as it does with the facts that affect manufactures, commerce, and agriculture, ought to be widely studied in a nation having such pronounced shopkeeping proclivities as the English. It is right and proper that those who are to be the custodians of our trade in future should know something about the manner in which physical and political surroundings affect industry and commerce, and about the conditions of success in the various industrial branches. Prof. Gonner treats these matters in a way likely to impress students. His manual is divided into three parts, the respective subjects of which are (1) commercial geography and its principles; (2) the geography of the chief products and others; (3) countries, their agriculture, industries, and commerce. Trustworthy statistics are plentifully distributed throughout the book, and they serve to give an idea of the relative importance of different countries as regards different commodities, as well as being useful for reference. Of course, no student would be expected to commit these tabular statements to memory. If the main facts contained in this volume are grasped by students intended for commercial careers, British commerce will undoubtedly be benefited.

Dynamometers and the Measurement of Power. By John J. Flather, Professor of Mechanical Engineering, Purdue University. (New York: John Wiley and Sons, 1892.)

A USEFUL practical treatise on this subject, in a convenient form for Technical Students, containing also the mechanical theory required in the calculations.

The author has himself carried out a notable experiment in the measurement of the power of a full-sized American locomotive, which was jacked up, and the power taken off by heavy supporting wheels; a valuable object-lesson for the pupils of his Experimental Laboratory of Purdue University. The long-continued measurement of the power, coal and water consumption, &c., of a large engine in full work—for instance of a steamer, the *Meteor* and others—is one of the most interesting and instructive that can be provided for a class of enthusiatic students of mechanical engineering. G.

Electric Light and Power. By Arthur F. Guy, A.M.I.E.E. Pp. 346. (London: Biggs and Co., 1894.)

SOME books, like the pedlar's razors, are made to sell rather than for use. Mr. Guy's volume is not one of these. It has been issued "for the purpose of placing on record useful practical knowledge obtained by the author during several years' experience of central-station work, together with brief explanations of the laws which govern the action of electrical apparatus in general use for electric lighting." This brief description shows clearly the ground covered. There are many similar works in the market, but we do not know of one better suited to give the manipulator of electric dynamos an intelligent knowledge of the forces with which he has to deal.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Prof. Boltzmann and the Kinetic Theory of Gases.

IN the discussion which followed the communication of my Report on Thermodynamics to the British Association at Oxford this year, Prof. Boltzmann made some remarks which appear to have been interpreted in a different light to what he doubtless intended. In the absence of any shorthand writer's verbatim report of the discussion, it is of course impossible to recall his exact words, but I feel sure that Prof. Boltzmann will be much astonished to learn that his statements are now widely circulated and quoted as being an authoritative admission that the Kinetic Theory of Gases is nothing more than a purely mathematical investigation, the results of which are not in accord with physical phenomena; in short, a mere useless mathematical plaything.

Is it likely that such an able physicist would have devoted so many years to the development of the theory, and would continue to work at it now if he regarded it in that light? Having had several conversations with him, both during and after the British Association meeting, I gather that his views are not nearly so pessimistic as the opponents of the kinetic theory would wish to maintain.

The statements were made in reply to a question as to how far the ratios of the specific heats of gases as given by theory accorded with the results of experiment. What I understood Prof. Boltzmann to imply was that his investigations treated the matter purely from a mathematical standpoint, but that the values he obtained by regarding the molecules of a gas as rigid bodies, viz. 1·6 for smooth spheres, 1·4 for smooth solids of revolution, and 1·3 for solids of any other form, accorded on the whole *very fairly* with the results of experiment. In that respect the kinetic theory stands on exactly the same footing as any other theory of mathematical physics. The evidence in favour of the fundamental assumptions of *any* theory necessarily rests on the agreement or want of agreement of the deductions with experience after due allowance is made for the fact that the conditions imposed by the mathematical difficulties of the investigation necessarily differ from those occurring in nature. I need only refer to Prof. Boltzmann's paper, "Ueber die Natur der Gasmoleküle" (*Sitzungsberichte der Wiener Akademie*, lxxiv. ii. 1876), for a more detailed account of his views on the question of the specific heats.

The objection which has been regarded by some as most antagonistic to the kinetic theory is that it does not afford an explanation of the spectra of gases. But is this duty required of it? If the luminosity of gases were due to vibrations of the atoms in the molecules, certainly there *would* be a difficulty about regarding the molecules as rigid bodies; but then such a hypothesis would preclude a gas whose molecules were monatomic from having any optical properties whatever. To my mind, the electromagnetic theory of light entirely relieves the kinetic theory from the burden which has been imposed on it by its opponents, since if (for example) we regard the molecules of a gas as perfectly conducting hard spheres, spheroids, or other bodies moving about in a dielectric "vacuum" (*i.e.* space devoid of *ordinary* matter), we shall be able to account for the spectra by means of electromagnetic oscillations determined by surface-harmonics of different orders without interfering with the assumptions required for explaining the specific heats of gases. There are, however, other questions on which I should be glad to see a continuation of the brilliant discussion which had to be curtailed from want of time at Oxford. G. H. BRYAN.

Instinctive Attitudes.

MY attention has been called to Mr. H. M. Stanley's remarks on instinctive attitudes in NATURE of Oct. 18. I have been for some years studying children's attitudes and expressions from the evolution point of view; and have from time to time taken photographs as opportunity presented itself. I have now a considerable number which I hope to publish in that connection. One of the series accompanies this, and bears on Mr. Stanley's remarks. It was taken in May last, representing my youngest child, then ten months old. She never crawled, but always progressed on all-fours; and this photograph, taken instantaneously, shows her mode of travel to and fro on the garden path. The interesting thing about it is this: that the gait is front and back legs on opposite sides, like a dog or a cat, not on the same side, like a camel—a result which the evolutionist would have predicted; though of course we show a relic of the same habit in walking, by swinging the arm on the opposite, and not on the same, side as the leg. In this photograph, too, the heel and toe action of the hind limbs is instructive.

One of my children, in addition to the ordinary crawl, used to progress in a sort of three-legged fashion—it used the left hand

and the right foot for the forward step, rested itself on the shank of the left leg tucked under its body, and this it used as a foot to bring forward its body for the next step. Sometimes this developed into a three-step mode of progression.

The bandaging, swaddling, carrying and wheeling about, which the civilised infant has suffered for many generations, no doubt partly accounts for the rarity of the quadrupedal mode of progression, by having hindered development of muscularity. The quadrupedal mode of progression indicates greater strength than the ordinary knee-crawl. S. S. BUCKMAN.

Cheltenham, October 24.

James Parkinson, the Author of "Organic Remains of a Former World."

IN a paper on the subject of museums, which was read in 1891 before the meeting of an association, James Parkinson is thus spoken of without any subsequent qualification of the statement made:—

"Finally, a private lottery was arranged for its disposal (the Leverian Museum), and in 1785 the prize was drawn by James Parkinson, *a dentist*, who took not the least interest in natural history or in museums."

As the scientific world seems profoundly ignorant as to what were the scientific qualifications and professional position of James Parkinson, the following facts may be worth publishing in NATURE:—

James Parkinson, who resided at No. 1 Hoxton Square, was not a dentist, but a surgeon. In Johnston's Directory for 1817 his address is thus given: "Parkinson and Son, Surgeons, No. 1 Hoxton Square." He had also an address in the Kingsland Road. His death is thus recorded in the *Gentleman's Magazine* of December 1824: "December 21st, in Kingsland Road, James Parkinson, surgeon, late of Hoxton Square." There *was* a firm of dentists in London, whose address in Johnston's Directory was as follows:—"Parkinson and Kidman, surgeon-dentists, 1 Racquet Court, Fleet Street"; but they had evidently no professional connection with James Parkinson.

The following list of works, &c., by James Parkinson, published by H. D. Symonds, Paternoster Row, is given at the end of a little book by him, of which the title is "Dangerous Sports; a Tale addressed to Children," printed for H. D.

Symonds, Paternoster Row, 1808. Their titles, which I briefly give, will amply prove his professional position:—

(1) "Medical Admonitions to Families." 5th edition.
(2) "Observations on the Excessive Indulgence of Children."
(3) "The Village Friend and Physician." 2nd edition.
(4) "The Way to Health."
(5) "The Chemical Pocket-Book."
(6) "Hints for the Improvement of Trusses."
(7) "The Hospital Pupil."
(8) "Observations on the Nature and Cure of Gout."
(9) "Remarks on Mr. Whitbread's Plan for the Education of the Poor."
(10) "Organic Remains of a Former World." Volume the First.

In addition to his "Organic Remains," Parkinson produced "Elements of Oryctology, an Introduction to the Study of Fossil Organic Remains," which appeared in 1822. A third edition was published in 1840.

Whatever may have been Parkinson's lack of interest in natural history when he acquired the museum, he certainly showed no deficiency in that respect when he produced his "Organic Remains of a Former World," one of the most valuable and interesting works of the kind that I know. For further information with regard to Parkinson, see the Introduction to Mantell's "Atlas of Fossil Remains," published by H. G. Bohn in 1850, in which Parkinson's splendid plates are reproduced. See also Allibone's "Dictionary of British and American Authors"; London, 1870.

On Chinese Beliefs about the North.

FROM a review in NATURE for the 27th ult. (p. 522) I have been led to conclude that the "Theory of the Northern Origin of the Chinese" enjoys the confidence of scientific men. Should this conclusion really be correct, the theory will give strong support to the view which occurred to me while reading the review.

By Sze-má Kwáng, a Chinese Prime Minister of great classic knowledge (died 1086), the Rite of "Fuh" (*i.e.* bringing back), anciently observed before changing the clothes of deceased parents, is detailed as follows:—"Take a clean suit of clothes prepared for the corpse up to the ridge of the roof; then *towards the north call three times 'Pray, return'*; then fold up and bring down the suit to clothe the corpse; *to detain the soul* thus brought back, fasten the suit with silk (silken band); before the burial offer to it viands and utensils with as much reverence as is due to the parents alive" (1). In this ritual I notice three primitive beliefs unitedly preserved: firstly, that the soul of the deceased could return if called, the belief current among the Hos, the Bank's Islanders, and the Fijians of modern times (2); secondly, that one could detain the soul from departing by fastening a garment while addressing to the deceased, as is meant by an old Japanese usage on occasion of meeting the *passing soul, i.e., ignis fatuus* (3). In the third place, as is the case with the Kookies (4), this ritual indicates the primitive Chinese belief in the *existence of their other world in the north.*

The Early Chinese system of cosmogony, which is now fragmentally but uniformly preserved in the books of two antagonistic religions, viz. Confucianism and Taôism, has its God of the North named "Hiuen-Ming," *i.e.* "Entering Other World" (5).

Cháng Hwá, a Prime Minister of encyclopædic erudition (killed 300 A.D.), mentions in his work a Taôist belief in the other world as extensive as 200,000 *lis* square, situated underground in the north (6). Another Taôist Eschatology, written in the 9th century A.D., relates that "the Emperor Yen-teh, who was created the 'Grand Imperial Master of the North,' governs all spiritual beings" (7). Most probably connected with these beliefs is a folk-tale of the "'South Dipper,' the life-registrar, and the 'North Dipper,' the death-registrar" (8), from which is derived a popular romance of Chau Yen's bribery to the latter star-god in order to have his destined longevity increased from nineteen years to ninety-nine (9).

The Yogâtchârya mystics of China define the north as "the point whereat all the works are doomed to finish," and hence "the point of entering Nirvâna" (10). A dispute about whether Chinese Buddhism in this case is entirely free from the taint of Celestial gloss, I am not qualified to decide.

Now let us return to Confucian literature. Confucius's own opinion regarding the other world appears of quite agnostic character, as is implied in his answer to Tze-lu (who inquired about the state of death)—"While you do not know life, what can you know about death?" (11); as well as in his answer to Tze-kung (whose question was about whether the deceased had consciousness)—"If you die, you will know; even then it will not be too late to know" (12). But it is in those ancient sages' tenets, which the great master preserved in his doctrine, that the early Chinese belief in the northern spirit-land had been so predominant, though tacitly implied, as to have caused an all-reaching *association of the North with everything related to Death.* So, early they styled the rooms containing ancestral tablets the "North Temples" (13), and by the name "North Hill" the graveyard has always been understood.

According to the "Tang-kung" (a portion of the *Book of Rites*), Confucius was buried in the northern part of the capital of Lu, and "the burial in the northern sides of towns was the persistent custom of the three 'classic dynasties,' *i.e.* Hia, Ying, and Chau" (14). Forcibly this statement reminds us of the Damaras, who place the corpse with the face towards the north, to remind them whence they originally came; and also of the Yncas, who, expecting to go to the east whence they came, turned the face of the corpse to the east; while the aboriginal Peruvians did not follow the same usage (15). In fact, we find in Chinese records certain abnormal examples, which indicate the stocks distinct from original Chinese; thus, two corpses of different sexes discovered from the mound of Prince Tsükü, a Hiung-nú by descent, are said to have had their heads turned eastwards (16).

Mr. Herbert Spencer, after reasoning from materials extensively collected, remarks: "Immigrant races have for their other-worlds the abodes of their fathers, to which they journey after death" (17); and unless they are an exception to this general rule, the Chinese, whose old customs and traditions have been shown to tend so much towards evincing their early belief in the northern spirit-land, *must have originally entered their present domain from the North.*

Also, in early Chinese speculations the north had been fixed on as the store and source of the originating principle "Yin" (or *Negativity*), and it has ever since been associated with everything of "negative" characters—*e.g.* reposing, obscuring, destroying, &c. Thus, in the symbolism of "Wu-háng" (the *Five Elements*), water and winter are posted at the north (18); of the nine divisions of the heavens the northern and the north-western are named respectively "Dark Heaven" and "Dusky Heaven" (19); of the five mountains worshiped by emperors the northernmost one is called "Eternal Mountain" (*Han Shan*), because all beings are doomed to eternal repose in the north (20); and referring to the then admitted axiom—"the north is the realm of slaughters and assaults"—Confucius once reproved Tze-lu for playing on a stringed instrument in the "northern tones" (21).

As there should be nothing other than Death that might combine in itself all conceivable characters of Negativity, it would seem quite reasonable to trace the origin of these associations of North and Negativity of Chinese speculations into the old custom of burying in grounds lying towards the north, which custom in its turn is easily traced to the early Chinese entrance from the north.

The Planting of Timber Trees.

IN Traill's sketch of the life of Shaftesbury (the first Earl), the following passage occurs in a letter from the Earl to the steward of his estates in Dorsetshire :—

"The best planting of timber trees is with nuts, acorns, seeds, and footsets, and not with young trees removed . . . In setting of chesnuts, acorns, and seeds [it is desirable] to steep them twenty-four hours in milk, which gives them a great advantage. . . . If siccamores [are planted] near my gardens, they will spoil all my fruit with the flies they breed. Therefore pray pluck up all the siccamores that are in the dry meadow behind my kitchen-garden, and in the room of every one of them plant a chesnut, a walnut, or a honey-broke oak."

Can any of your readers inform me whether the soaking of seeds in milk is now, or ever has been, extensively practised, also what is meant by a "honey-broke oak"?

ALFRED W. BENNETT.

Rhynchodemus Terrestris in England.

THE credit of the first discovery of this land-planarian in England lies not with Sir John Lubbock, as Dr. Scharff stated, but with the late Rev. L. Jenyns (Blomefield), who, in his "Observations in Natural History," 1846 (p. 315), makes some interesting remarks on the "Ground Fluke" (*Fasciola terrestris*) and its occurrence in the woods at Bottisham Hall, a locality searched with success by Mr. Harmer.

Rhynchodemus terrestris is widely distributed in England, and I have found it in Derbyshire, North Lancashire, and Westmoreland, under moist conditions and on a limestone substratum.

Any additions to the limited number of land-planarians in Europe are of considerable interest, and mention may therefore be made of Prof. v. Graff's description (*Bull. Soc. Zool. France*, xviii. 1893, pp. 122–3), of *Rhynchodemus pyrenaicus*, n. sp., from St. Jean de Luz, which is not alluded to by Dr. Scharff.

F. W. GAMBLE.

Owens College, Manchester, October 26.

Tan-Spots over Dogs' Eyes.

THE shepherds in some of the east counties of Scotland used to call their black-and-tan collies four-eyed dogs, which agrees so far with Mr. Peal's observations. These collies, twenty years ago, were much in demand. Now they are hardly allowed prizes at shows, and are becoming scarce; black and white, pure white, and, more commonly, brown dogs being greater favourites.

J. SHAW.

A CRITICISM OF THE ASTRONOMICAL THEORY OF THE ICE AGE.

IN a communication to the British Association at Oxford, I gave an outline of a method of obtaining a limit to the direct effect on terrestrial temperature of the diminished winter sun-heat during epochs of great eccentricity, the conclusion being that that effect had been enormously exaggerated, and that the astronomical theory of the Ice Age was really but a vague hypothesis, having no sound physical foundation.

It will be remembered that Dr. Croll's theory is shortly this: In the long northern winters in the time of great eccentricity, far less sun-heat is received than at present; the *direct* effect of this decrease in sun-heat is a *proportionate* decrease in terrestrial temperatures, or, more properly, a proportionate decrease in the excess of terrestrial temperature over the temperature to which the earth would fall in the absence of all sun-heat. So far Croll and Sir Robert Ball, the later expounder of the theory, agree. But now they part company. Croll affirms that the lowering of temperature thus calculated would be quite insufficient, and that it is the *indirect* effect of this fall of temperature (chiefly the effect in disturbing oceanic circulation) which gives rise to the additional lowering of temperature necessary for the production of an Ice Age. Ball, on the other hand, affirms that the direct lowering of temperature due to diminished sun-heat is amply sufficient to cause an Ice Age. I use the word *affirms* advisedly, because neither writer assigns any reason. Apparently Croll's reason was that he thought he could see additional causes, which if they existed must have contributed to the effect, and also that previous writers had said that the direct effect of the change in sun-heat would not be sufficient; while Ball seems to have considered that he had strengthened Croll's argument so much that the new form of the theory was as strong without the ocean currents, as Croll's was with ocean currents. It does not seem to have occurred to either writer to ask what change in temperature would be necessary in order to produce an Ice Age, so that they might see if the cause they assigned would be sufficient; yet one would have thought this was the first step towards formulating a theory.

The point in reference to which the two authors employ numerical calculation is in obtaining the fall of terrestrial temperature due to a reduction of sun-heat. The problem is, of course, very complicated, and one would expect that the most approved principles of physics would be employed. Not at all. The physics is founded on an incidental remark of the astronomer Herschel in his "Outlines of Astronomy" (edition of 1869), where he assumes that the radiation of a body in space is *proportional* to its absolute temperature. Yet it has for many years been known to physicists that the radiation increases faster than the temperature, and in 1880 or 1881 what is now known as Stefan's law was published, namely, that the radiation increases as the fourth power of the absolute temperature. This would make an enormous reduction in the calculated fall of temperature due to a diminished supply of heat—*it would reduce it to one-fourth* of the amount obtained on the erroneous assumption employed by Croll and Ball alike. For if temperature be solely due to sun-heat, the heat radiated, say $A\theta^4$, where θ is the absolute temperature, must be equal to that received, say S, or

$$A\theta^4 = S,$$

hence

$$\frac{d\theta}{dS} = \frac{1}{4}\frac{\theta}{S},$$

whereas the law of direct proportionality assumed by Herschel, and adopted by Croll and Ball, gives

$$\frac{d\theta}{dS} = \frac{\theta}{S},$$

a result four times as great as that obtained above—

Turning now to Croll's form of the argument, we find one very remarkable inconsistency, which I think is no bad illustration of the special pleading which characterises that ingenious writer. When, in the first place, he desires to show how great may be the midwinter fall in temperature due to diminished sun-heat, he thus employs the argument I have criticised above :—

Let T_p be the present excess of midwinter temperature at the latitude of the British Isles above the temperature of space, *i.e.* above the temperature to which the earth would fall if all sun-heat were to cease, and S_p the quantity of sun-heat at present received on that latitude on Midwinter Day, and let T_g and S_g be the corresponding quantities for the supposed glacial winter. Then, on Herschel's hypothesis, T_g is to T_p as S_g is to S_p. Having in that way got an enormous fall of temperature, Dr. Croll goes on to say that a vast proportion of our midwinter temperature in these isles is due, not to sun-heat received by us, but to heat carried to us by ocean currents. These ocean currents, he argues, will be diverted in the supposed glacial period, and thus there will be a *further* great fall in temperature. The argument for this double diminution of temperature is, of course, utterly invalid. If a great proportion of our winter-heat be not due to sun-heat, then a considerable loss of sun-heat would not affect our winter temperature very much, and the first argument is wrong; if it be all due to sun-heat, then the first argument is right, and the second wrong.

Nor do we find much greater accuracy in Sir R. Ball's exposition of the theory. He is, indeed, much fairer than Croll in taking the winter temperature as proportional to the *average* daily supply of winter sun-heat, instead of the Midwinter Day sun-heat, for it is evident that the adjustment of temperature to sun-heat could not take place instantaneously. But in another particular he seems greatly to *understate* the case for the theory. His method of calculating the average daily sun-heat is to take the winter heat over the *whole northern hemisphere*, and divide it by the number of days in winter, and similarly for the daily summer sun-heat. He applies the average thus obtained to calculate variations in temperature in the latitude of the British Islands. But when we remember that the theory of the Ice Age is the theory of the temperature of the latitudes from about 45° N. to lat. 70° N., or, if you like, to the pole, it appears quite misleading to use numbers obtained from the sun-heat received by the *whole hemisphere*. For the proportion which the total winter sun-heat we receive in these Isles bears to the total summer-heat is expressed, not by Ball's numbers 37 and 63, but by the very different numbers 25 and 75. The great disparity between these numbers, contrasted with the temperate character of our climate, enables us to see how futile it is to appeal to our imagination, as Ball does, to conceive what vast differences of climate must be produced by differences in the daily receipt of sun-heat.

"If," he says, "a double supply of heat [63 measures] be poured in like a torrent during the short season [the 166 days of the short summer] while the single supply [37 measures] is constrained to do duty over the long season [the 199 days of the long winter], then an intolerable climate is the result. The total quantity of heat received on the hemisphere in the course of a year is no doubt the same in each case, but its unsuitable distribution bespeaks a climate of appalling severity—an Ice Age, in fact."

How untrustworthy this style of argument is, will appear when it is pointed out that in order to get a latitude in which as large a proportion as 37 per cent. of the annual sun-heat is received in the coldest 199 days, we have to go as far south as Madrid, Naples, Constantinople, New York, or Pekin! Yet we are asked to believe that this distribution, approximately two measures in 166 days, and one in 199 days, will produce "a climate of appalling severity—an Ice Age, in fact." ("Cause of an Ice Age," p. 135.)

There is another form in which the numerical method is applied by Ball, the result of which, so far from supporting the astronomical theory, would, if true, appear to me to be conclusive against it. The present mean annual range of temperature in Great Britain is about 20° F., and this, according to Ball, is caused by the disparity in the daily receipt of winter and summer sun-heat, acting against the mitigating causes. In the epoch of great eccentricity the disparity will be much greater, and instead of the range of 20° F. we shall have a range of 28° F. ("Cause of an Ice Age," p. 131.) Ball then goes on to say that such proportionate changes "are quite large enough to imply profound differences in the climatic condition. It is to be observed that, generally speaking, the coldest places are those of the greatest mean annual range. We are therefore entitled to infer that the effect of such a change in the eccentricity as we have supposed, would be to increase the range, lower the temperature of the hemisphere, and thus induce the glacial period."

One would not consider such a statement out of place in a popular series if it embodied the result of an inquiry too complicated to be explained except in technical language; but that is not the case here, nor can the conclusion be admitted as in the slightest degree probable. In fact, so far from our being entitled to infer that such an increase in the mean annual range would induce a glacial period, it appears to me that the mere fact that in all continental climates north of Lat. 40°, the present range is greater than 28° F., entitles us to infer that such a range would have no power whatever to induce an Ice Age.

The problem of ascertaining the effect of different astronomical conditions upon terrestrial temperatures is too complicated for accurate solution. How far the temperature at any place depends on the sun-heat falling on the outer layers of the atmosphere at the place (which is all that we can find by calculation), and how far on the transference of heat by ocean or air currents, must always remain to some degree uncertain, but that the latter exert a preponderating influence seems evident for two reasons—first, that while the sun-heat in each season remains the same from year to year, the seasons themselves vary enormously (we have cold summers and hot summers, warm winters and cold winters, all with unchanged conditions of sun-heat); and second, the difference between summer and winter temperatures is, in northern latitudes, but slight when compared with the difference between the quantities of winter and summer sun-heat received. Hence it appeared to me that no modification of Croll's method of calculating differences of temperature due to differences of sun-heat could be relied on, for our knowledge of the transference of heat from one region to another is too slight to enable us to allow for its effect in our equations. But there is another method which seems very reliable, especially when applied to the British Isles, or any region where warm ocean currents flow from the south. Not, indeed, that the method enables us to calculate the lowering, if any, of temperature in the epoch of great eccentricity, but it appears to enable us to fix, with some degree of certainty, *a limit to the direct effect of the diminished winter sun-heat*.

The method depends on comparing those regions which now receive given allowances of summer and winter sun-heat with the regions which, in the epoch of great eccentricity, received the same allowances. If, following Croll, we suppose the temperature on Midwinter Day to depend on the sun-heat received on that day, we find that latitudes 90°, 80°, 70°, 61°, 52°, and 43° now receive the same sun-heat on Midwinter Day as latitudes 90°, 80°, 70°, 60°, 50°, and 40° received on the Midwinter Day of the most extreme eccentricity. In other words, instead of Dr. Croll's fall of 45° F. (I omit his decimal point), the midwinter temperature of London would, in the supposed glacial epoch, be lowered to that of Manchester at present, for Manchester is about 2° north of London. If, following Ball, we take the average daily heat in winter as the basis of comparison, we should find that latitudes 90°, 81°, 71°·3, 61°·7, 52°·4, and 43°·3 receive in the present winter the same daily average of sun-heat as latitudes 90°, 80°, 70°, 60°, 50°, and 40° received in the long winters of greatest eccentricity. Or, finally, if we adopt the hypothesis, too favourable to the astronomical theory, that the widwinter temperature depends on the daily average through the 199 coldest days of the year, we find that latitudes 84°·5, 74°, 63°·5, 54°, and 44°·2 ought now, so far as direct sun-heat is concerned, to have the same midwinter temperature as 80°, 70°, 60°, 50°, and 40° had in the supposed glacial epoch; and when it is observed that the summers in these latitudes were then considerably hotter than the summers in the former latitudes, 84°·5, 74°, 63°·5, 54°, and 44°·2 now are, the utter inadequacy of the astronomical theory to explain the vast differences in temperature must surely be admitted by any reasonable mind.

But when we take account of the ocean currents, it seems probable that instead of being lowered the winter temperature in the British Isles would be raised in the long winter of the supposed glacial epoch. For the Gulf Stream flows at about four miles per day between the Azores and Norway—that is, about ten degrees of the earth's surface in six months, so that we may fairly suppose the midwinter heating of these countries to be dependent on the summer heating at about Lat. 40°–45°. Now during the 166 days of the short summer in the epoch of great eccentricity, these latitudes received a greater daily average of heat than any latitude, even the equator, now receives in an equal time. Hence it is likely that the midwinter receipt of ocean heat in that epoch was much greater than at present. This seems to harmonise with the present condition of Mars. So far, indeed, as the evidence from the condition of Mars is admissible, it seems to be quite inconsistent with Croll's view.

A paper dealing more fully with the mathematical portion of the subject will shortly appear in the *Philosophical Magazine*, and a more exhaustive criticism of Croll's and Ball's works will be found in the January number of the *Geological Magazine* for 1895.

It is satisfactory to know that although the astronomical theory of the Ice Age has been steadily gaining an assured position among the semi-scientific public—one sees it referred to as the most generally accepted explanation in such diverse works as Nansen's "Journey across Greenland," and Laing's "Human Origins"—the rising school of geologists are strongly opposed to it, as contradicting the geological evidence.

EDWARD P. CULVERWELL.

NOTES.

THE President and Council of the Royal Society have this year awarded the medals as follows:—The Copley Medal to Dr. Edward Frankland, for his eminent services to theoretical and applied chemistry; the Rumford Medal to Prof. James Dewar, for his researches on the properties of matter at extremely low temperatures; the Davy Medal to Prof. Cleve, of Upsala, for his researches on the chemistry of the rare earths; and the Darwin Medal to Prof. Huxley, for his researches in comparative anatomy, and especially for his intimate association with Mr. Darwin in relation to the Origin of Species. The Royal Medals have been awarded to Prof. J. J. Thomson in recognition of his contributions to mathematical and experimental physics, especially to electrical theory; and to Prof. Victor Horsley for his important investigations relating to the physiology of the nervous system and of the thyroid gland, and to their applications to the treatment of disease. We learn as we go to press that the Queen has signified her approval of these awards.

THE following is a list of those who have been recommended by the President and Council of the Royal Society, for election into the Council for the year 1894–5, at the anniversary meeting on November 30:—President: Lord Kelvin. Treasurer: Sir John Evans, K.C.B. Secretaries: Prof. Michael Foster, Lord Rayleigh. Foreign Secretary: Sir Joseph Lister, Bart. Other members of the Council: Dr. Andrew Ainslie Common, William Crookes, Francis Darwin, Dr. Andrew Russell Forsyth, Sir Douglas Galton, K.C.B., Prof. Alexander Henry Green, Sir John Kirk, K.C.B., Prof. Horace Lamb, Prof. Edwin Ray Lankester, Prof. Alexander Macalister, Prof. John Henry Poynting, Prof. Arthur William Rücker, Osbert Salvin, Prof. J. S. Burdon Sanderson, Dr. Thomas Edward Thorpe, William Henry White, C.B.

WE regret to note the death of Prof. M. Duchartre, the eminent French botanist. He was in his eightv-fourth year.

THE Société nationale d'Horticulture de France is organising an international exhibition of horticultural products and industries, to be held in May 1895.

THE death is announced of Dr. Francesco Gasco, Professor of Comparative Anatomy and Embryology in the University of Rome.

SIR D. A. LANGE, who was appointed in 1858 the constructor of the Suez Canal, has just died, and was for some years director in England of that work. He was a Fellow of the Royal Geographical Society, the Society of Antiquaries, and of other learned societies, and the author of several important books connected with the Suez Canal.

A BLUE-BOOK has been issued containing Commissioner H. H. Johnston's report of the first three years' administration of the eastern portion of British Central Africa. The report deals with the physical geography of the country, its meteorology, agricultural conditions and resources, minerals, and fauna, with the characteristics of the native races, and is altogether of considerable scientific value.

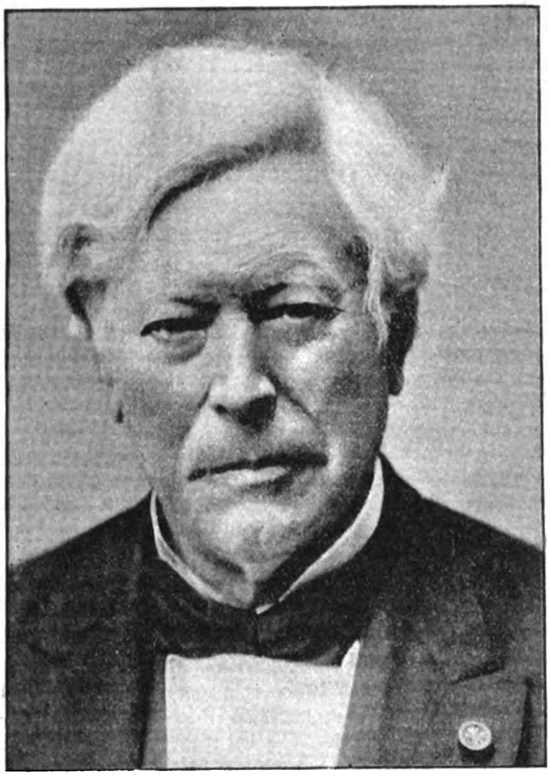
AFTER the great earthquake shocks in Greece, last spring, a committee was appointed to make an examination of the Parthenon, in order to ascertain what damage the temple had sustained. The committee reported that the building had been seriously injured, and that there was great risk in allowing it to remain in its present dangerous condition. They recommended, therefore, that immediate steps be taken to strengthen it. Reuter's correspondent at Athens now reports that the Archæological Society, at a meeting called to consider the question, have voted an unlimited credit for the purpose of effecting the necessary repairs.

MR. H. C. RUSSELL, has sent us an account of the travels of three bottle-papers used for determining ocean currents. One was thrown into the sea near the Crozet Islands in March 1893, and was found in September 1894 between Cape Banks and Cape Northumberland. The mean daily rate of this appears to have been nearly eight miles. Two other papers travelled over much the same course on the south coast of Australia, at mean rates of six and nine miles a day. The interesting point is that three current papers should pass over more or less the same track, and agree so well as to the rate of the current. The paper that made only six miles a day was hampered with a heavy frame of wood, which had been put round it as a protection when it should reach the coast.

THE arrangements for the new session of the Society of Arts are now announced. The session commences on November 21 with an address from the Chairman of the Council, Major-General Sir John Donnelly. The first regular paper will be by Mr. Hiram Maxim, on his "Experiments in Aeronautics," and this will be followed the succeeding week by one by M. Hermite, on "The Electrical Treatment of Sewage." Two other papers—one by Mr. Thomas Ward on "Salt," and one by Gen. Michael on "Forestry"—will be read before Christmas. A number of papers for meetings after Christmas are also announced. Six courses of Cantor Lectures are promised, of which the first is by Prof. Vivian Lewes on "Explosives." There will be, as usual, a course of Juvenile Lectures after Christmas; the lecture this year is by Prof. C. V. Boys, F.R.S., his subject being "Waves and Ripples."

M. A. DELEBECQUE, of Thonon, sends us a small pamphlet on the lakes of Dauphiné. These lakes are very numerous, many of them being mere tarns or lagoons, and some, although figuring as sheets of water on the large-scale maps, are frequently dry. He gives an account of his soundings in the lakes of Bourget, Aiguebelette, Paladru, and the smaller lakes of the plateau and mountain regions. As to the origin of these basins, M. Delebecque believes that many of the smaller are due to glacial action, either erosion or the irregular accumulation of moraine stuff. He does not confirm Forel's theory of the origin of the lake of Bourget by the barring of a lateral valley by the alluvium of the Rhone, but is inclined rather to look upon it as a result of movements in the crust. The origin of the other lakes is more obscure, but some appear to be probably due to movements of the strata, while others arose from the barring of lateral valleys by detritus. Particulars of temperature observations and analyses of the water of various lakes are given, and M. Delebecque concludes with an appeal to the local scientific societies of Dauphiné to initiate systematic observations on the lakes of the district.

MONSIEUR FAYE, the celebrated French astronomer, who lives in Paris, has recently received a handsome token of the admiration of his colleagues. All the members of the Bureau des Longitudes, together with their president,



Monsieur de la Grye, assembled in his house, and presented him with a silver enamelled tablet, on which Astronomy and History are represented offering a medallion to the most useful of careers. It bears the following inscription: "To Hervé Faye, President of the Bureau des Longitudes, 1874-1893. The homage of his colleagues." The two allegorical figures are sitting in the clouds, and Astronomy is pointing to the comet which was discovered by the illustrious astronomer. This interview greatly affected Monsieur Faye, who had only retired on account of the new law, opposing the perpetuity of the presidency.

MR. J. THEODORE BENT AND MRS. BENT leave London to-morrow, November 9, for an exploring journey in Arabia. They go first to Karachi, and thence by steamer to Muskat on the Gulf of Oman, where the land journey commences. It is Mr. Bent's intention to cross Arabia from east to west, and, in doing so, to revisit the Hadramut Valley, and continue his archæological researches there.

MR. TREVOR-BATTYE, to whose arrival at Archangel we referred last week, has telegraphed to the *Times* a detailed account of his experiences on his visit to Kolguef Island. He landed on the north-west coast of the island on June 21, at the mouth of the river Gosina, accompanied by Thomas Hyland (a bird-skinner) and a spaniel. A few days later they started to cross the island, and found the journey very difficult on account of the bogs and snow-filled ravines, and the severity of the weather, which was either cold and foggy or intensely hot, calling out swarms of mosquitoes. Birds were abundant, but the only mammal seen was a fox. At length, after a week's travelling, a party of Samoyedes and many reindeer were found near Chum. Mr. Trevor-Battye made this his headquarters until August 20, gaining much information as to the language and customs of his hosts, and assisting them in their hunting. He records the capture of 300 Brant geese in one net, and on another occasion the slaughtering of 300 reindeer. A Russian trader arrived who had visited the island for thirty-five successive years, and he remained a month transacting business with the Samoyedes. On September 18 Mr. Trevor-Battye sailed with the Russians for the mainland, and experienced bad weather on the way, and much difficulty in navigating the shallow water near shore. His orthodox companions attributed this difficulty to the presence of a Samoyede idol which was very displeasing to St. Nicholas; but Mr. Battye clung to his trophy, though at some personal risk. After landing, there was a four days' journey in sledges to Oksina, and a three days' boat trip up the Pechora to Ust Tsilma. It was the worst time of the year for travelling, as the land was marshy, and the rivers, unnavigable on account of floating ice, were not yet frozen over. However, Mr. Trevor-Battye and his companion struggled on in sledges or carts, and, after adventures with wolves and all manner of delays, ultimately reached Archangel in excellent health. Kolguef Island appeared to be of alluvial formation with no trace of massive rock, being possibly a remnant of the delta of a great river. The coast-line is quite different from that shown on the chart. Extensive zoological and botanical collections were secured.

AT the annual meeting of the Royal Cornwall Geological Society, held at Penzance, on November 2, Mr. Howard Fox, the President, reviewed the progress made during the past twelve months towards the elucidation of the many unsolved problems of Cornish rocks. Mr. F. J. Stephens had found radiolarian cherts in the Meneage conglomerate, and on the mainland near Mullion. Mr. Ussher, of the Geological Survey, had traced Upper Devonian strata in the St. Germans district, west of the Tamar. The President himself had found similar strata west of Padstow, and a peculiar rock at Dinas Head in the same district, which contained nearly ten per cent. of soda. In its compact form it might easily be mistaken for a chert, but it passed into a nodular variety showing spherulitic structure. Whether it were a soda felsite (keratophyre) or a sedimentary rock altered by contact metamorphosis, such as the Adinole of the Hartz, was a question on which petrologists were not as yet in absolute agreement. The evidence from sedimentary rocks in contact with greenstone on Cataclens and Round-hole Points indicated a sedimentary origin, as did General McMahon's notes on the sections he had examined. Crinoidal remains had been found in black shales of the Ordovician district of Veryan, interbedded with radiolarian cherts, but these shales had as yet yielded no typical zonal fauna. He (Mr. Fox) had sent some sections of the carboniferous cherts of East Cornwall to Dr. Hinde, who found those from Carzantic Quarry, near Launceston, full of radiolarian casts, with one instance of structure. Further investigations were being made in this direction by Mr. Ussher and himself. In conclusion, he drew attention to the unwise practice of taking away shingle from beaches faster than it was being reproduced by nature.

IN connection with the controversy over preformation and epigenesis which at present agitates the biological world, we may draw the attention of our readers to a series of articles contributed by Wilhelm Haacke to the *Naturwissenschaftliche Wochenschrift* (Bd. ix. Nos. 32–38, Aug. and Sept. 1894), under the title "Schöpfung und Wesen der Organismenform." The writer passes under review the various theories of the origin and development of organisms which are associated with the names of Albrecht von Haller, Wolff, Blumenbach, Goethe, Lamarck, St. Hilaire, Darwin, Weismann, Roux and other biologists, and criticises them from a standpoint not far removed from that of Oscar Hertwig. The synthetic views of the author do not give one the impression of finality, but, as a historical *résumé* of the oscillations and tendencies of thought upon some fundamental problems in biology, Dr. Haacke's essay is distinctly interesting.

THE importance, both from economic and from scientific points of view, of a thorough knowledge of the floating fauna and flora round our coasts is so generally recognised, that our readers will be interested in a recent article which, in concise form, furnishes a number of valuable data upon this subject, and must considerably facilitate the further prosecution of similar researches. The article forms part of a report contributed by Mr. W. Garstang to the current number of the *Journal of the Marine Biological Association*, in which the author gives a record of his observations upon the fauna during 1893–94, and upon the breeding seasons of marine animals at Plymouth, and also submits an attempt to construct a calendar of the changes observable in the floating fauna from month to month in the same locality. *Der Anfang ist das Schwer*, and marine biologists familiar with the seeming fickleness of marine phenomena know well the powers of discrimination and the experience necessary for the production of accurately generalised information under this head. It is most satisfactory, therefore, that the valuable work upon our north-eastern fauna, which Prof. M'Intosh has conducted for many years past at St. Andrews, should be now supplemented by the observations of another competent naturalist on our south-western shores. If, as we hope, arrangements can before long be made for carrying on continuous observations at the young, but promising, station at Port Erin, and on the west coasts of Ireland and Scotland, we shall in good time be equipped with data of the most valuable kind for determining many problems connected with the natural history of our migratory and other fishes.

THE second of the *Tufts College Studies* embodies the results of an investigation of the development of the lungs of Spiders (*Agelena nœvia* and *Theridium tepidariorum*) by Orville L. Simmons. The author's interpretations differ entirely from those of Jaworowski, already noticed in our columns (October 25, p. 621). He finds that the lungs arise as infoldings of the posterior surface of the appendages of the second abdominal somite, the lung cavity being essentially a pit in the body-wall at the base of, and behind, the appendages in question. The development of the lamellæ agrees strikingly with Kingsley's observations on the origin of the gills of *Limulus*, and lends considerable support to Prof. Lankester's well-known theory. The tracheæ develop behind the next pair of limbs at the apex of a similar depression of the body-wall. In their earlier stages these appendages show on their posterior surfaces certain feeble undulations, which the author regards as aborted lung- or gill-lamellæ. The tracheal twigs arise as simple ingrowths comparable, in the author's opinion, with the infoldings which produce the lamellæ. Mr. Simmons concludes that the lung-book condition is primitive, the tracheæ of Arachnids being derived from it. How far he is right in this conclusion, and how far (if at all) Jaworowski has gone wrong, are questions that we hope will not long remain undecided.

A REDETERMINATION of the temperature of greatest density of water has recently been carried out by M. de Coppet, who gives an account of his results in the *Annales de Chimie et de Physique*. On account of the very slow change of density about that temperature it is difficult to determine it within a hundredth of a degree Centigrade. The method adopted was a modification of that of Despretz. A number of thermometers were mounted in the lid of a cylindrical water vessel with their bulbs at various distances from the bottom, and symmetrically disposed about the axis. On immersing the vessel in a cold water bath, a current was set up, passing down along the sides and ascending in the centre. After a while the current stopped, and then was reversed. The course of the current could be followed by the readings of the thermometers. The water having the greatest density would sink to the bottom, and the temperature of the lowest bulb would be approximately that of greatest density. But the temperature at which the lowest thermometer stopped for a time was higher on cooling than on heating. The curves exhibiting the two series of changes are, however, symmetrical, and give the temperature of maximum density as 3°·982 by the hydrogen thermometer under a pressure of one atmosphere.

A SIMPLE method of obtaining light of different wave-lengths for use in polarimetric work is described by Landolt in the *Sitzungsberichte* of the Berlin Academy, No. 38. White light from an Auer's glow-lamp is passed through different absorption cells containing coloured solutions which can be readily procured. Details are given of the preparation of five such cells, by means of which red, yellow, green, light blue, and dark blue light may be obtained. Examined spectroscopically, the light is in each case found to consist of a band, and is not by any means monochromatic; if, however, the rotation be less than 20°, or, with one or two of the cells, even if it be considerably greater, the field of the polarimeter remains apparently uniform in tint. The wave-lengths with which the bands may be taken to correspond, were determined by using the cells in a set of observations on the rotation of quartz, and comparing the results with those obtained for the rotation of quartz by Broch's method. The wave-lengths were thus ascertained to be not far removed from those of the Fraunhofer lines C, D, E, F, G. The instrument employed was a Laurent half-shadow polarimeter fitted with a Lippich's polariser. A simple method of this kind has long been required for the speedy investigation of rotatory dispersion. It is also of importance to have a ready means of obtaining light of short wave-length, which is of especial service when determining the rotatory power of feebly active substances.

IN a paper communicated to *L'Electricien* (Paris), M. G. Darriens gives an account of some recent experiments he has made on the chemical reactions which take place in the ordinary lead accumulator. To get an idea of the chemical state of the negative plate of an accumulator, the author treated a given weight of the negative plate of a fully-charged accumulator with hydrochloric acid, and measured the volume of hydrogen evolved. He then measured the volume of hydrogen evolved when an equal weight of ordinary sheet-lead was dissolved in hydrochloric acid, and obtained practically the same number as before. This experiment seemed to indicate that the negative plate of a charged accumulator consists of metallic lead, in a very finely-divided state, and that a charged accumulator simply represents an ordinary voltaic cell in which lead is the negative element. In order to test this point, the author has examined the behaviour of several forms of primary battery in which finely-divided lead is used as the negative metal. In the case of a Daniell cell consisting of a copper plate in a saturated solution of copper sulphate and a plate of spongy lead in dilute sulphuric acid, the liquids being separated by an ordinary porous pot, the mean of several experiments gave the value 0·64 volt as the electromotive force. A calculation of the electromotive force of this cell, based on the heats of formation of the different substances, gives 0·3 volt, so that it would appear as if lead in this very finely-divided state evolved more heat when it entered into combination than under ordinary conditions. If this supposition is true, it is necessary to add 0·34 to the figures calculated for ordinary sheet-lead, to allow for this "allotropic" modification of the metal. If we apply this correction to the observed electromotive force (1·6 volts) of an element consisting of PbO_2 and pure lead, we get the quantity 1·94 volts, which represents the electromotive force of the element PbO_2 and spongy lead. The above values can be utilised to calculate the quantity of heat necessary to convert ordinary lead into spongy lead, the value obtained being 7·4 calories. With a Daniell cell, as described above, in which the spongy lead had a surface of one square decimetre, and weighed 440 grms., the mean electromotive force was 0·57 volts and the capacity 13·75 ampere-hours, the internal resistance being about 0·12 ohms. This form of cell is subject to the same objection as the ordinary form of Daniell, namely, that after a time the copper-sulphate solution diffuses through the porous pot, and the copper is deposited on the negative metal.

THE filtration of water on a large as well as on a small scale has acquired quite a different significance since the bacteriology of water has sprung into existence; and it is as a useful, because impartial contribution to this subject, that we welcome Surgeon-Major Johnston's short treatise on "the relative efficiency of certain filters for removing micro-organisms from water." The investigations here recorded were made as qualifying work for the degree of D.Sc. at Edinburgh University, and the experiments were carried out in the Public Health Laboratory of the University. The filters examined were those known as the Atkins patent water filter, Maignen's table "Filtre Rapide," the Nordmeyer-Berkefeld filter, and the Pasteur-Chamberland filter. The first two filters are described as useless for sterilising water, both of them not only allowing "micro-organisms to pass through the pores," but affording "a suitable nidus for the growth and multiplication of micro-organisms, which are found in much greater numbers in the filtered water than in the unfiltered." The "Berkefeld" and "Chamberland" filters were more elaborately examined. The "Chamberland" cylinder selected was one intended for slow filtration, and in comparing the results obtained with it and the "Berkefeld" cylinder respectively, it must be borne in mind that the rate of filtration through the latter was 5½ times greater than through the former, although after twenty-four hours' continuous filtration, the rate was only 1¼ times greater. Major Johnston's opinion, based on his examination of these particular cylinders, is that "the Pasteur-Chamberland filter is the best and only one on which reliance can be placed for permanently sterilising water." An important point, and one which has been overlooked by the author, is the temperature of the room in which the filters were kept whilst under examination. Freudenreich found that a higher or lower temperature had a marked effect on the efficiency of the Chamberland filter. It is to be regretted that in a thesis of this kind, purporting to have a bibliography, the author should have entirely neglected to mention or refer to, in any way, a large number of important investigations on these particular filters published during the last few years in various foreign journals.

MR. G. J. SYMONS has contributed to part ii. of the Report of the Chicago Meteorological Congress, an interesting summary of early English meteorological literature, embracing the years 1337-1699. He only deals with some fifty books and pamphlets contained in his own library, but his special knowledge of meteorological bibliography enables him to give some useful particulars about these old works. We can only briefly refer to a few of them here. In the Bodleian Library at Oxford there is (as far as is known) the earliest continuous weather record in the world, containing observations by the Rev. W. Merle from January 1337 to January 1344. A few copies of a translation of this work were printed in 1891. These observations show that the weather at that time was very similar to what it is now. In 1670, "The Shepheard's Legacy" was printed. This work is excessively scarce, and is the earliest edition of what has since been reprinted many times as "The Shepherd of Banbury's Rules for judging the weather." In 1671 appeared "A discourse concerning the Origine and Properties of Wind," &c. This treatise is noteworthy as being probably the first in which the theories of the winds are compared with details of the trade winds, monsoons, &c. In 1696 a work entitled "New Observations on the Natural History of the World of Matter," &c., by the Rev. T. Robinson, was published. It gives the earliest description yet known of the strong local wind known in Cumberland as the *helm wind*. The subject of this wind has been brought before the Royal Meteorological Society on several recent occasions, and that Society appointed a committee to collect information upon it.

THE November number of the *Journal* of the Chemical Society has been published. It is almost entirely taken up with abstracts of papers published in other journals.

MESSRS. R. FRIEDLÄNDER AND SON have sent us their *Naturæ Novitates*, Nos. 14-19, 1894, and No. xxx. of the quarterly list of their new publications. The lists are invaluable to those who wish to keep in touch with recent scientific literature.

THE *Quarterly Journal* (No. 201) of the Geological Society contains several papers on the geology of Africa. Dr. J. W. Gregory describes the glacial geology of Mount Kenya; Captain H. G. Lyons, the stratigraphy and physiography of the Libyan Desert; and Mr. H. Draper, the principal physical and geological features of South-eastern Africa, and the occurrence of dolomite in South Africa. There are seven other papers in the *Journal*, and sixteen plates.

WE have received parts iv. to vii i. of the third volume of the *Transactions* of the Leicester Literary and Philosophical Society, extending from July 1893 to July 1894. The Society holds general meetings, at which lectures of a more or less popular character are given, and sectional meetings for the reading and discussion of technical papers. Its object is to cultivate literature, science and art, and, judging from the reports, good work is being done in each of these directions.

IT is well known that Dr. A. Bernthsen's "Text-book of Organic Chemistry" is an excellent elementary account of the principles of organic chemistry. Dr. George McGowan's translation of the work, published by Messrs. Blackie and Son, was reviewed in these columns in December 1889 (vol. xli. p. 172). A second English edition, revised and extended by the author and the translator, has now appeared. It is virtually a translation of the fourth German edition, published last year, and therefore various chapters have been recast in order to include new developments of their subjects.

MESSRS. R. AND J. BECK have just issued an illustrated catalogue of microscopes, object-glasses, and other apparatus for which they are famed. In it we find descriptions of microscopes, from the large binoculars (which some investigators declare to be almost indispensable for certain researches) to the smaller instruments suitable for bacteriological and clinical work, and the useful petrological microscopes. The microscope, like the telescope of the present day, bristles with innumerable accessories, and Messrs. Beck's catalogue appears to contain most of these adjuncts. A copy of the catalogue will be sent, post free, on application.

THE Report of the Weather Bureau of the United States for the year 1893, which has just reached this country, shows that a general reorganisation has been effected, and that the work has been carried on successfully. A very important publication of the results of observations during 1891 and 1892, from upwards of 2000 stations, has been recently issued. Every means is taken to popularise the science; the daily weather map is now issued at seventy-two stations of the Weather Bureau outside of Washington, the number distributed annually being over two and a half millions. The circulation of the weekly weather crop bulletins of the State services has also greatly increased; and continues to be the most valuable feature of State weather service work. A large number of railway companies co-operate with the Bureau in distributing the daily weather forecasts by telegraph over their lines, and whistle-signals are used to a considerable extent in some States. The subject of seasonal forecasts is receiving the careful attention of the Bureau, since the meteorological service of India has indicated a path by which useful results can perhaps be reached. The report also states that Prof. Bigelow continues his studies of magnetism with sufficient prospect of success to justify the time and labour expended. The library of the Bureau now consists of nearly 20,000 books and pamphlets, and the bibliography of meteorology comprises more than 65,000 titles.

CULTIVATORS and admirers of roses will be interested in "Rhodologia"—a discourse on roses and the odour of rose—by Mr. J. C. Sawer, published by W. J. Smith, North Street, Brighton. Too much attention is generally given to the development of colour, form, and size of the flower, little heed being paid to the great variety of perfumes generated in the beautiful petals. Mr. Sawer says that there are experienced gardeners who can discriminate many varieties of roses in the dark, recognising them by their perfumes. The pure odour of rose is best represented by *Rosa Damascena*, Miller, and *R. centifolia*, Lin. The art of distilling roses appears to have originated in Persia, and dates from about 1612. In 1684 it is certain that otto of rose was manufactured on a large scale at Shiraz. Otto of rose was known in Europe, however, about forty years sooner than in the East, where its manufacture was first practised. We learn that at the present day the odorous products of the rose are extracted in Bulgaria, France, Germany, and to some extent in India, Persia, Tunis, Algeria, Morocco, and Egypt. The rose cultivated in Bulgaria for the otto is a variety of *R. Damascena*—the red damask rose. *R. centifolia*, which in English gardens is grown as the cabbage rose or Provence rose, is cultivated commercially in the south of France. Mr. Sawer brings together in his pamphlet a mass of details of interest to students, as well as to manufacturing chemists and buyers of rose-products. Rose growers (both amateur and professional) should certainly read "Rhodologia."

Two remarkable substances, carbazide or carbonyl nitride, CON_6, the nitrogen analogue of phosgene gas $COCl_2$, and di-urea, $CO(NH.NH)_2CO$, the carbonyl derivative of dihydrazine, are described by Prof. Curtius and Herr Heidenreich in the current *Berichte*. The former compound, which is constitutionally formulated $CO(N_3)_2$, is found to be readily produced when the recently described hydrochloride of carbohydrazide, $CO(NH.NH_2HCl)_2$, is treated with a cold aqueous solution of sodium nitrite. The reaction is a relatively simple one, proceeding according to the equation:—

$$CO(NH.NH_2HCl)_2 + 2NaNO_2 = CO(N_3)_2 + 2NaCl + 2H_2O.$$

Carbazide as thus produced is a colourless oil of most explosive character. It explodes with great violence when merely touched. When the oil is dissolved in ether, and the solution is allowed to evaporate over calcium chloride, the pure substance CON_6 is left in long brittle crystals, which usually explode spontaneously in a bright light, but may occasionally be preserved for some little time before disruption. The substance is extremely volatile, and the vapour possesses a most penetrating and stupefying odour, reminding one simultaneously of phosgene gas and azoimide, N_3H. Its composition is readily proved by saponification with alkalies, which convert it into salts of azoimide, which can be precipitated by silver nitrite. It also reacts with aniline in alcoholic solution to produce carbanilide and free azoimide. The second compound described in the communication, di-urea, $CO\left\langle\begin{matrix}NH.NH\\NH.NH\end{matrix}\right\rangle CO$, is produced when the compound $\begin{matrix}NH.COOC_2H_5\\ |\\ NH.COOC_2H_5\end{matrix}$, also recently described by Prof. Curtius, is heated to 100° in a tube with hydrazine hydrate. Di-urea crystallises readily from water in monoclinic prisms melting at 270°. It behaves as a strong monobasic acid which is capable of expelling carbonic acid from carbonates. The ammonium salt, $C_2H_3N_4O_2.NH_4 + H_2O$; barium salt, $(C_2H_3N_4O_2)_2Ba + 3H_2O$; silver salt, $C_2H_3N_4O_2Ag$; and diammonium (hydrazine) salt, $C_2H_3N_4O_2.N_2H_5$, have been prepared and analysed. It is a very stable substance, quite different in this respect from the explosive carbazide above described. When heated, however, with concentrated hydrochloric acid in a sealed tube to 150° it is decomposed into carbonic acid and hydrazine.

$$CO(NH.NH)_2CO + 2H_2O = 2CO_2 + 2N_2H_4.$$

The hydrazine remains combined with the hydrochloric acid in the form of a chloride, presumably diammonium chloride N_2H_5Cl.

THE additions to the Zoological Society's Gardens during the past week include a Brown Capuchin (*Cebus fatuellus*) from Guiana, presented by Mr. Graham S. Pownall; two Common Marmosets (*Hapale jacchus*) from South-east Brazil, presented by Mr. D. B. Macdougall; two Black-backed Jackals (*Canis mesomelas*) from South Africa, presented by Mr. Claude Southey; three Crossbills (*Loxia curvirostra*), two Parrot Crossbills (*Loxia pityopsittacus*), an European White-winged Crossbill (*Loxia bifasciatus*), a Yellow Bunting (*Emberiza aureola*), two Northern Marsh Tits (*Parus borealis*) from Russia, presented by Captain A. Newnham; a Double-ringed Dove (*Turtur bitorquatus*) from Java, presented by the Hon. Rose Hubbard; a Black Salamander (*Salamandra atra*), European, presented by Mr. Maurice Suckling; a Bonnet Monkey (*Macacus sinicus*) from India, two Lions (*Felis leo*, ♂ ♂) from Africa, deposited; a Golden Plover (*Charadrius pluvialis*), three Dunlins (*Tringa alpina*), European, purchased; a Spotted Pigeon (*Columba maculosa*), a Triangular-spotted Pigeon (*Columba guinea*), two Vinaceous Turtle Doves (*Turtur vinaceus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

A COMET ON THE ECLIPSE PHOTOGRAPHS OF 1893.—A year ago Prof. Schaeberle announced that the eclipse photographs taken by him at Chile in April 1893, showed a comet-like structure in the corona near the sun's south pole. The photographs taken by the British observers in Brazil and Africa were examined in order to see if they showed the cometary object, but nothing could then be made out. It is well known, however, that faint objects can be easily found when the observer knows what can be seen, and where to look for it. Prof. Schaeberle and Prof. Holden were confident that a comet was photographed upon the corona of the 1893 eclipse, and, with the idea of obtaining confirmation of the discovery, the latter sent Mr. W. H. Wesley copies from negatives obtained at Chile and Brazil, having marks upon them showing the exact position of the object in question. These guides have fulfilled their purpose, for Mr. Wesley says, in the *Observatory*, that they clearly point out a cometary structure in the corona. The object is extremely faint, and, unless particular attention is drawn to it, appears like a forked coronal ray. Evidently the only way to prove that the object was really a comet was to measure its angular distance from the moon's limb on the photographs taken at the different eclipse stations. Mr. Wesley has done this, and he finds that the distances are: Chile, 29′; Brazil, 36′; Africa, ± 47′. Therefore, it is concluded "the evidence of motion relatively to the sun, given by the comparison of the plates taken at the three stations, seems to place the nature of Prof. Schaeberle's interesting discovery beyond a doubt."

THE TRANSIT OF MERCURY.—The transit of Mercury across the sun on Saturday, November 10, is a matter of more interest to American than to European astronomers. The planet will enter upon the sun's disc at 98° from the North point, counting towards the East, and will leave at a point 50° from the North, counting towards the West. It will reach the sun's limb at five minutes to four in the afternoon; but as the sun sets at Greenwich about twenty minutes later, there will not be much opportunity for observation in London. In America, however, if the weather is favourable, the planet will be observed during the whole of the five hours it will take in transiting. The following are the Greenwich Mean Times of the phases of the transit:—

		h.	m.	s.
Ingress, exterior contact	Nov. 10	3	55	31·2
Ingress, interior contact	,,	3	57	15·4
Least distances of centres (4′ 26″·8) ...	,,	6	33	48·5
Egress, interior contact	,,	9	10	26·4
Egress, exterior contact	,,	9	12	10·4

MIRA CETI.—Mr. Fowler writes from South Kensington to draw attention to the fact that this remarkable variable will be suitably placed for observations during its progress to the next maximum. According to the *Companion to the Observatory*, the date of minimum was September 24, and the maximum may be expected about February next. It will be of great interest to obtain a spectroscopic record during the rise to maximum, with special reference to the time of appearance of the bright lines of hydrogen, which have been seen near the time of maximum.

Mr. Fowler observed the spectrum on October 24, with the three-foot reflector, and it did not then differ from the spectrum of such a star as α Herculis, in which the hydrogen lines are not known to appear bright. The bright part of the spectrum which is coincident with the carbon band near λ 5165 was relatively less bright, however, than when it was observed near the last maximum.

RETURN OF ENCKE'S COMET.—It is reported that Encke's comet was observed at Rome by Prof. Cerulli, near the predicted place, on November 1. According to a search ephemeris given in the *Astronomische Nachrichten*, No. 3260, for Berlin midnight, the comet's place for November 8 is R.A. 22h. 59m. 30s. Decl. + 12° 32′ 18″. The comet passes perihelion next February.

TWO VARIABLE STARS.—In a *Wolsingham Observatory Circular*, No. 40, dated October 30, the Rev. T. E. Espin says: "The variability of two red stars, R.A. 0h. 49·0m. Decl. + 58° 1′ and R.A. 1h. 49·8m. Decl. + 58° 46′ has been definitely ascertained."

OBSERVATIONS OF MARS.

A LARGE proportion of the October number of *Astronomy and Astro-Physics* is devoted to articles on Mars, illustrated by several coloured plates. Schiaparelli's map of Mars forms the frontispiece; Prof. Schaeberle contributes nine drawings of the planet; and there are three plates containing drawings made at the Lowell Observatory, Flagstaff, Arizona, by Mr. Percival Lowell, Prof. W. H. Pickering, and Mr. A. E. Douglass. The following statement, from an article by Prof. Pickering, is a chronological summary of the more important facts and discoveries relating to Mars. It is chiefly compiled from Flammarion's monograph on Mars, and should be of special interest at the present time:—

272 B.C. The first known observation of Mars is recorded in Ptolemy's Almagest.

1610. The phases of Mars were discovered by Galileo.

1659. The first sketch showing surface detail was made by Huyghens. He also suggested a rotation in 24 hours.

1666. Cassini determined the rotation of Mars to take place in 24 hours 40 minutes. He also observed the polar caps, and "he distinguished on the disc of Mars, near the terminator, a white spot advancing into the dark portion, and representing without doubt, like those of the moon, a roughness or irregularity of the surface." This latter statement is curious, but the effect was undoubtedly due to irradiation, since his telescope was entirely inadequate to enable him to observe such a delicate phenomenon.

1777. With the exception of Huyghens, Hooke, and possibly Maraldi, no one succeeded in making recognisable sketches of the surface detail upon Mars for over a century, until Sir William Herschel took the matter up in this year.

1783. Sir William Herschel detected the variation of the size of the polar snow caps with the seasons, measured the polar compression, and determined the inclination of the axis of the planet to its orbit.

1785–1802. Schrœter made an extended study of the planet. His drawings are upon the whole rather better than those of Herschel. He discovered among other things the very dark spots to which Prof. Pickering has referred in his publications as the Northern and Equatorial Seas. He, however, supposed them to be clouds.

1840. Beer and Maedler published the first map of the planet, assigning latitudes and longitudes to the various markings. On this map are indicated the first canals, and the first of the small lakes, so many of which have been discovered during the last few years. The canals are Nectar and Agathodaemon and portions of Hades and Tartarus. The lake is Lacus Phoenicis. Their map is the first satisfactory representation of the entire surface of the planet. The only region which previous observers had clearly distinguished was that in the vicinity of the Syrtis Major.

1858. Secchi made a careful study of the colours exhibited by the planet.

1862. Lockyer made the first series of really good sketches of the planet, showing all the characteristic forms with which we are now so familiar. His drawings, and also those of some of the other observers, give the first indications of the appearance of the central branch in the Y, so called by Secchi.

1864. Dawes detected eight or ten of the canals.

1867. Huggins detected lines due to the presence of water vapour in the spectrum of Mars.

1867. Proctor determined the period of rotation of Mars within 0·1 second.

1877. Hall discovered the two satellites of Mars.

1877. Green made a very excellent series of drawings of the planet, superior to anything which had preceded them.

1877. Schiaparelli made the first extensive triangulation of the surface of the planet, and added very largely to the number of known canals.

1879. Schiaparelli detected the gemination of Nilus, the first known double canal.

1882. Schiaparelli discovered numerous double canals, and announced that the appearance formed one of the characteristic phenomena of the planet.

Mr. Percival Lowell reports the observations of Mars made at the Lowell Observatory, in continuation of those recorded in our issue of September 13. The subjoined abstract of the paper raises some interesting points. The suitability of the site of the observatory may be judged from the fact that the planet has been observed at Flagstaff every night, with but few exceptions, since the beginning of June. British astronomers would like to be blessed with similar favourable opportunities.

A noteworthy feature of Mr. Lowell's previous paper was the large area occupied by the dark regions on Mars, while those singular, tilted peninsulas that are so generally represented connecting the continents with the islands to the south were conspicuous by their absence. At that time one continuous belt of bluish-green stretched unbroken from the Hour-glass Sea to the columns of Hercules, or rather to where this pass should have been, for it was not visible. Now (September 10) the continuity is cut. Hesperia has reappeared, and it has done this in just the way we should expect it to show were it land drying off by a sinking of the general water level. Simultaneously, the region formerly occupied by the polar sea and the region to the north of it from having been blue, has now become for the most part reddish yellow. This reappearance of Hesperia and change of colour of the regions farther south is not due to increasing distinctness of vision consequent upon the nearer approach of the two planets. Had Hesperia been then of anything like the brightness it is now it could not have been invisible. Furthermore, Eridania is at present one of the brightest parts of the disc, not only as it comes round into view, but in mid-career across. Last, and not least in significance, the polar sea has shrunk to a thin line in keeping with the diminished size of the polar cap itself. All this water has gone somewhere.

What may be the condition of these seemingly amphibious lands, whether they be marsh chiefly water at one time and dry land at another; or whether their dark colour be due to vegetation which sprouted under the action of the water, and then died when it withdrew, is a moot point. Mr. Lowell's opinion is that it is half and half; that the transference of the water is chiefly a surface one, and that the layer of water is almost everywhere so shallow as to be soon drained off. His reasons for believing the aqueous circulation to be a surface one are many. In the first place, with the exception of certain peculiar appearances near the south pole, there is no evidence of anything like clouds or mist observable upon the planet, nor has there been since the observations began. On the contrary, all parts of the surface seem to be revealed unveiled. For an aerial circulation the only supposition at all feasible is thought to be that of a heavy, nightly dew, advanced by Prof. Pickering. There are strong reasons in the probable constitution of the Martian atmosphere for believing this possible. But in view of certain facts connected with the canals, and referred to later, the dew theory seems to be improbable.

As to how much of the dark areas are water, and how much vegetation, there is as yet no evidence to decide. Prof. Pickering has made some ingenious polariscopic observations to this end, but the difficulties inherent in the process are such as to preclude definite answer as yet. At first the polar sea seemed to show evidence of polarisation, confirming what we knew before of its watery character. Later the lakes, polar sea, and dark areas alike revealed no trace of it. Inasmuch, then, as there is every reason to suspect the polar sea, at least, to be water, we are left in doubt as to the adequacy of the instrumental means to detect at present such minute phenomena.

Since Mr. Lowell's last paper, irregularities have been detected at Flagstaff in the Martian terminator. These fall for the most part under two heads, of which one is practically new. It consists of certain polygonal flattenings first observed on June 30 by Mr. Douglass. Since then these irregularities have become so conspicuous that it is now difficult not to see one of them in the course of an hour's observation. Sometimes they show as simple slices shaved off the terminator, a paring of the planet's surface; sometimes they appear bordered by enclosing projections. They range from twenty to forty degrees wide. But the suggestive thing about them is that they show almost invariably upon that part of the terminator where the darker of the dark regions is then passing out of sight.

At first sight it might seem as if the observed appearance were directly due to the darker areas lying at a lower level than the rest of the surface. But the connection is not so simply direct. For Mr. Lowell points out that were it due to a zone of low-level lying between zones of higher altitude, it could be observed only as a limb effect in this case still further diminished by the cosine of the phase angle, a quantity far too small to be observable.

Nor will variations in slope explain the phenomenon. For to have an area show as a depression on account of its slope, either the areas on both sides of it must be rising in altitude, or the area itself must be falling in height, and this state of affairs could not go on for ever unless the surface were an impossible spiral. So that the persistency of this flattening is thus unaccounted for.

Prof. Story has suggested that these dark areas have smooth surfaces such as water would have. In this case, remarks Mr. Lowell, the reflection from them, by which alone they would be perceptible, would diminish much more rapidly from the centre to the side than would be the case with regions having rough surfaces, such as deserts. It may be added that though a rough surface, properly constructed, might obliterate itself by its own shadows, this could not happen to either a desert or a forest or a grass-grown plain.

The second kind of irregularities are projections, or small notches, such as are visible upon the lunar terminator; only that the Martian ones are much less pronounced. They are probably due to mountains which seem to be of no great height. The first of these was observed by Mr. Douglass on June 30. An especially prominent one he noted on August 19. It consisted of a projection flanked by a long shadow cutting into the planet obliquely. He measured the shadow's length at 35″. Taking the obliquity into account, this seems to imply a range the length of whose projection would be about 2″. It is difficult to say how much of this is due to irradiation; especially as each observer differs. The best tests Mr. Lowell has been able to make give a probable average of about five-sevenths of a tenth of a second of arc with the power then applied, about 640. Calling the terminal projection of this range therefore ·13″, its height appears to be about 3700 feet. But the smallness of the quantity measured and the uncertainty of the factor of irradiation renders the result largely indefinite.

A consequence of the slope on the effect of these mountains is interesting. For an elevation need not appear as such. What would show as a projection on the nether side of the terminator would appear as a depression on the hither one.

Interesting plateaus were observed on two occasions by Prof. Pickering. One of these lies in Phætontis not far from the columns of Hercules, which thus seem to have been most appositely named. Both plateaus rise abruptly, are surprisingly level on top, and stand at about the same height, a height which from the reduced measurements does not probably exceed 2600 feet.

On Mars the second kind of irregularity is less common than the first, and the elevations indicated are apparently never what we should call high. We may therefore conclude that the Martian surface is, as compared with our terrestrial one, relatively flat.

Certain whitish patches have been observed on the planet, first by Prof. Pickering on August 16, and subsequently several times by both Prof. Pickering, Mr. Douglass, and Mr. Lowell. Prof. Pickering calls them clouds. To Mr. Lowell, appearances thus designated are of two kinds. The one, certain whitish, flocular patches not far from the pole, may possibly be cloud; for they present a peculiar aspect, not like snow, nor yet like *terra firma*. No motion, however, has been seen in them. The others are merely certain bright spots on the general surface of the planet. These are not whitish, but yellowish, and will probably do very well for the more arid, dried-up tops of the land. They likewise do not move, and, furthermore, show always the same appearance day after day as regularly as their regions come round. Many of them were equally conspicuous at previous oppositions, and have been chronicled by various observers. Their contours are neither shifty nor indistinct, but as sharp-cut as those of any other region.

Most suggestive of all Martian phenomena are the canals. Were they more generally observable, the world would have been spared much scepticism and more theory. They may, of course, not be artificial, but observations made at the Lowell Observatory indicate that they are. For it is one thing to see two or three canals, and quite another to have the planet's surface mapped with them upon a most elaborate system of triangulation.

In the first place, they were, at the season of writing, bluish-green, of the same colour as the seas into which the longer ones all eventually debouch. In the next place, they are almost without exception geodetically straight, supernaturally so, and this in spite of their leading in every possible direction. Then they are of apparently nearly uniform width throughout their length. What they are is another matter. Mr. Lowell thinks, however, that the mere aspect is enough to cause all theories about glaciation fissures or surface cracks to die an instant and natural death.

But it is their singular arrangement that is most suggestively impressive. They have every appearance of having been laid out on a definite and highly economic plan. They cut up the surface of the planet into a network of triangles instantly suggestive of design. What is more, at each of the junctions there is apparently a dark spot. This feature seems to be invariable, as, on closer approach, junction after junction turns out to have one. The larger of these appear on Schiaparelli's chart as lakes. But there would seem to be a small infinity of smaller ones. A short half-hundred of them were seen at Arequipa in 1892, and others have recently been detected at Flagstaff. For example, an important new canal, which runs from the western end of the sea of the Sirens to Ceraunius, and which in view of its point of departure Mr. Lowell is induced to call the Ulysses, passes through three of these small dark spots on the way, one at each junction. One of these was seen at Arequipa and elsewhere in 1892; the other two are new discoveries. The region of the Lake of the Sun is especially fertile in canals. In one of the drawings which accompanies the paper here summarised, thirty-one canals are to be seen, counting each line between junctions as a separate canal. Of these seventeen are among those in Schiaparelli's chart, while fourteen are not. Of the twelve lakes in the figure, five are not down on his chart. This is thought not, in general, to be the result of change, though changes there apparently have been after proper discount has been made for difference of observations and of drawing. First and foremost, the Golden Chersonese has vanished; the land of Ophir now forms the continental coast-line. Secondly, Icaria has entirely altered in contour, resembling now an open fan about the Phœnix lake for pivot. Phætontis has shrunk to one-third of its former width—as represented in Schiaparelli's chart. Eosphoros no longer enters Phœnix lake at the point opposite Pyriphlegethon, but farther to the west. But the strangest transformation of all is that of the Phasis, which has apparently obligingly become two (not geminated in the technical sense) to suit both the old and the new state of things. There is now a canal running in the same direction as the old Phasis, but not to the southern end of Phætontis; and there is another one running to the southern end of Phætontis, but not in the same direction as heretofore. This attempt to carry out two apparently important ends by self-multiplication is not a common characteristic of inanimate nature—a point which Mr. Lowell holds is worth consideration.

Mr. A. Stanley Williams contributes to the November *Observatory* an account of his observations of Mars up to October 20. With regard to the canals Mr. Williams says:—"By taking advantage of every favourable opportunity, fifty-one canals have been observed up to the present time [October 20]. These include most of those shown in Prof. Schiaparelli's latest map that could be properly observed at present, and in addition three others not marked in the map. Generally speaking there is no difficulty in certainly identifying the canals, with the exception of a few which are situated far north, and consequently are too close to the limb to be distinctly observed. The general accuracy of the map is very striking, and I have often been strongly impressed by the very thorough manner in which Prof. Schiaparelli's work has been done. It is most rare to come across the trace of a canal not marked in his map, and the positions of objects are usually very reliable."

In the October number of our contemporary, Mr. Williams stated that Phison was probably double. Later observations, however, have shown it to be only single, the apparent gemination being probably caused by the existence of a feeble, unrecorded canal running parallel to it, and about midway between it and the coast bordering the Kaiser Sea. Agathodæmon and Araxes were seen intensely double on three or four nights in September. Chrysorrhoas was also seen double, but this canal appeared as an inconspicuous object compared with Agathodæmon and Araxes. In September Mr. Williams saw Amenthes as a narrow inconspicuous and apparently single canal. At the beginning of October, however, the object appeared as a very broad, dusky, double canal. Ganges is another broad, conspicuous double canal, the duplicity of which, according to Mr. Williams, is so obvious as to be apparent on almost any night on which observations are possible.

Referring to the small dark spots designated lakes, Mr. Williams says:—"Several more of these curious dark spots have been seen. Lacus Phoenicis on a good night appears as a small, nearly round, almost black spot, resembling the shadow of a satellite of Jupiter when in transit. On one night a feebler companion spot was seen just preceding it. Lacus Tithonius is a similar definite and nearly black spot, with a feebler companion following it. In a fine drawing of Mars, dated September 5, Mr. Cammell shows Lacus Moeris as a minute dark spot, with Nepenthes as a narrow definite line, and so I have seen them on several nights lately. Lacus Tritonis is a similar spot. At the junction of the canals Amenthes (following component), Thoth, and Astapus, there is also a little dark spot. The dark spot at the north end of the Ganges, known as Lacus Lunæ, has been rather perplexing. On several nights there was an evident appearance of duplicity about it, though it was impossible to say with certainty in which direction it was double. At length, however, the mystery was cleared up, the lake having been seen distinctly double on September 29 at right angles to the direction of the Hydraotes. The streak or bridge dividing the lake into two was bright yellow."

The varying appearances presented during October by the Mare Cimmerium, and the extensive region lying to the north of it, leads Mr. Williams to think that a great development of cloud or mist has lately taken place on Mars. His observations suggest "that cloud and mist formations are much more extensive and common on Mars than is generally considered to be the case."

THE ELECTRIC CONDUCTIVITY OF PURE WATER.

THE difficulties besetting the preparation of water free from the last traces of dissolved impurity cannot be better illustrated than by the attempts which have been made to ascertain the electric conductivity of the pure liquid. At the outset it has to be remembered that the conductivity of water is exceedingly small. As the result of the most recent observations it has been found that one millimetre of water has at 0° almost the same resistance as 40,000,000 kilometres of copper of the same cross-section; consequently a copper wire having the same resistance and sectional area as one millimetre of water would be long enough to encircle the earth one thousand times. From the difficulty of preventing the introduction of small quantities of dissolved material into the water, and from the large diminution which such impurities exercise upon the resistance, there is probably no physical constant for which such widely varying values have been given as for the electric conductivity of water.

If the conductivity of mercury be taken as 10^{10}, prior to 1875, the following values had been ascribed to water by the observers named:—80, Pouillet; 70, Becquerel; 15, Oberbeck; 4·5, Rosetti; 2·16, Quincke; and 1·33, Magnus. In 1875, Kohlrausch succeeded in reducing the observed conductivity to 0·71, or a value only 1/120th of that given by Pouillet. The large diminution thus brought about was no doubt due, for the most part, to the improved methods employed in obtaining purer samples of water. In Kohlrausch's experiments pains were taken not only to remove organic matter and any volatile alkaline or acid impurities from the water, but also to ensure that in its subsequent treatment contact with glass was avoided, the purified water being distilled through a platinum condenser into a platinum resistance-cell. The next important modification in the treatment of the water was again introduced by Kohlrausch in 1884. The whole of the above measurements had been made upon water distilled under ordinary conditions, and thus in presence of air; he therefore proceeded to ascertain what alteration in conductivity took place when the water was rendered air-free. For this end he employed a glass apparatus resembling in construction the so-called "water-hammer." A glass bulb of some 150 c.c. capacity, which served as a retort, was connected by a glass tube with a small glass receiver fitted with platinum electrodes. In this receiver the resistance of the water was measured by the use of a galvanometer and a continuous current, as the latter was so feeble that no appreciable effect was produced by polarisation. The glass connecting-tube was provided with a vertical branch, through which water, or liquids to clean the apparatus, could be introduced. Having admitted a quantity of purified water into the bulb, the vertical tube was then connected with a mercury air-pump, the pump set in action, and the water repeatedly shaken. A flask of cooled sulphuric acid was also put into communication with the evacuated enclosure to absorb water vapour, and thus promote partial distillation of the water. When dissolved gases had been removed, the vertical tube was sealed, and water was then distilled from the bulb into the receiver, the former being immersed in a bath at a temperature of 30° to 40°, and the latter in a cooling mixture at from 0° to −8°, the temperature being kept as low as possible in order to diminish the solvent action of water on the glass. The value obtained in this way for the conductivity at 18° was 0·25, or a number which is practically only one-third of that given by water distilled in air.

Small as this number was, it was not supposed to represent the actual conductivity of water, because experiment showed that the conductivity altered rapidly with the time, owing to the dissolution by the water of material from the glass receiver, and from the electrodes. The correctness of this supposition is strikingly verified in a communication recently made by Kohlrausch and Heydweiller to the Berlin Academy of Sciences (*Sitzungsberichte*, March 1894). One of the pieces of apparatus used in 1884, and described above, had been allowed to stand filled with water for some ten years, and, apparently from long contact with the water, the glass has become much less soluble than it is under ordinary circumstances. Indeed, during the time necessary for an observation the conductivity does not alter appreciably, and only rises by 0·01 in a day. The method of experiment employed is similar to that just described, the main modifications consisting in additional precautions to obtain the water air-free, and in freezing the purified water prior to its introduction into the apparatus. This method of freezing, suggested first by Nernst, is of value in eliminating volatile impurities which might distil over with the steam. The smallest value now found for the conductivity is ·0404 at 18°, or a number which is only 1/2000th of the original value given by Pouillet, and only one-sixth of that obtained in the same apparatus in 1884.

Since with each improvement the value for the conductivity has been largely reduced, the question which naturally arises in connection with this last result is, how closely can it be supposed to approximate to the truth? Indeed, seeing that the conductivity is so very small, it might fairly be suspected that absolutely pure water is itself a non-conductor, and that the observed conductivity is merely due to the presence of a slight trace of impurity. As it seems almost impossible to answer this question by purely experimental methods, theoretical aids have to be employed, and by means of the hypotheses involved in the new theory of solutions, Kohlrausch and Heydweiller proceed to show that pure water is actually a conductor, and that its conductivity can be ascertained from their observations. The method they employ is briefly as follows:—According to Arrhenius, if water is a conductor, the reason for this is that certain of its molecules exist dissociated into the ions H and OH. Moreover, the magnitude of the conductivity depends upon two factors: firstly, on the number of dissociated molecules; and secondly, on the velocities with which the ions travel. The conductivity varies with the temperature because the number of dissociated molecules, as well as the ionic velocities, increases with the temperature. From these theoretical views, although it is not possible to estimate the actual value of the conductivity, yet the rate at which it should vary with the temperature may be ascertained. For, in the first place, according to van't Hoff, the extent of the dissociation should vary with the temperature just as it does in a dissociating gaseous system; and in the second place, the velocities of the ions H and OH may readily be obtained at different temperatures from measurements on dilute aqueous solutions, such as those of KOH, HCl, and KCl.

Now, Kohlrausch and Heydweiller measured at 18° the temperature-rate of change for a series of samples of water of different degrees of purity, and also the conductivity of two samples of very pure water at temperatures between −2° and 50°. They then assumed that the observed conductivity was really a sum, being composed of the conductivities of pure water and a dissolved impurity. They were thus enabled to show how it is possible, by making use of the rate of change as deduced by theory for the single temperature of 18°, to obtain from their observations the conductivity of pure water at different temperatures.

The first result arrived at, is that the temperature-function of the conductivity over the entire range from −2° to 50° agrees within the limits of the experimental errors with the function predicted by theory. This, as the authors remark, is one of the most remarkable confirmations yet adduced of the validity of the hypothesis of the new theory of solutions. The second and the most important conclusion for the question under discussion is, that at 18° the conductivity of pure water has in all probability the value 0·0361. The smallest value actually observed, it will be remembered, was 0·0404. The impurity present in the sample affected the conductivity, therefore, by 0·0043, or by some 10 per cent. If this impurity were of the nature of a salt, as in all likelihood it is, the amount which would exert this effect would not require to be more than a few thousandths of a milligram per litre. We have here, therefore, the remarkable result that an impurity of this nature, if present to the extent of only a few parts per thousand million, is capable of influencing the conductivity by as much as 10 per cent. of its value. This, together with what has already been said, leaves little question that of all the physical constants of water, there is none which is so sensitive to small traces of dissolved impurity as its electric conductivity.

J. W. RODGER.

NEO-VITALISM.[1]

A QUARTER of a century ago, du Bois-Reymond headed the revolt of Mechanicalist Biology against the Vitalism of Johannes Müller. From Bichât to Magendie, from Johannes Müller to Schwann, the pendulum swung backwards and forwards; but it was reserved for du Bois-Reymond, in his now famous Berlin addresses, together with Ludwig and Helmholtz, to expose the fallacies of vitalism, and establish physiology on a mechanical basis.

In the present address he takes up arms against the "new vitalism," which since the discoveries of Heidenhain *re* activity of cell in secretion, *versus* mere mechanical diffusion, has made a new departure, based on a partial misconception of these secretory activities. The position of the debate as it now stands will be best shown by an abstract of Prof. du Bois-Reymond's recent manifesto.

From Descartes and Leibnitz, until they encountered their first opponent in Magendie, vitalistic theories were paramount. During this period "vital force" was conceived as the attribute of the soul in distinction to the body, or confused with the so-called "nervous principle," with animal heat or electricity.

Johannes Müller and Schwann again fought out the question; even the discovery by Schwann of independent cell-life in the organism failing to convince Müller that his views were erroneous. The overthrow of vitalism was reserved for Ludwig, whose autographic methods strengthened the physical side of experimental physiology. He came forward as the champion of anti-vitalism, and the same position was taken up by many of Müller's immediate pupils. The fundamental difference between this and all previous criticism lay in the physico-mathematical training of the antagonists, which enabled them to detect the πρῶτον ψεῦδος of vitalism. This prime error is the misconception of "force." Force is not an entity existing apart from matter; it is ultimately a mathematical concept, standing for the physical changes which alone can be known to us. The atoms are not a truck to which the forces can be harnessed; their attributes are eternal, integral, inalienable. Helmholtz said that without a rational conception of nature, scientific research would have no meaning; vital force, however, is unthinkable.

The fundamental distinction between organic and inorganic bodies has not been adequately recognised. In crystals, and dead bodies generally, matter is in static equilibrium, stable, indifferent, or labile; in living organisms, the equilibrium is dynamic. As in heat, and electrical diffusion, the rise and fall of current is balanced; there is constant metabolism. And metabolism, as well as the conservation of energy, present insuperable difficulties to the vitalist. Heat and muscular work, ciliary and amæboid movements, not least electricity, cannot be generated in animals otherwise than by conversion of potential into kinetic energy, by oxidation of carbon and hydrogen. For this nutritive matters—air, warmth, moisture, and for plants light (the "integrating stimuli" of J. Müller) are indispensable

[1] "Ueber Neo-Vitalismus." Von du Bois-Reymond. Sitzungs Berichte der Akademie der Wissenschaften zu Berlin. Oeffentliche Sitzung zur Feier des Leibnizischen Jahrestages vom 28 Juni, 1894.

conditions. And we must further compare the speed of organic processes with those of the crystal—quiescent to all eternity, unless disturbed by external forces. One of the finest conceptions of modern science is that the dynamic equipoise in the life of the individual corresponds to the cycle of living matter in all nature.

Labile equipoise is, however, preponderant in the organism. And here is the simplest explanation of the reaction which Müller held peculiar to living beings—excitability. The specific energies yielded up by living things in response to stimulus, amount to nothing more than the mechanical reaction of stored-up energy which we find, *e.g.*, in a chronometer. A repeating clock, in its specific reaction to stress or strain, heat or cold, moisture or dryness, electrical or chemical influences, presents a close analogy to the living muscle.

A final blow, it seemed, was dealt to vitalism by Darwin's "Origin of Species," which, through natural selection and the survival of the fittest, accounted rationally for existing variations. Thus the controversy was to all appearance ended. Of late, however, on anatomical rather than on physiological grounds, a new school of vitalism has arisen. By a somewhat strained conclusion from the labours of Schwann and Heidenhain, it is asserted that the processes deriving from elemental organisms are too vast in relation to the latter to be accounted for on mechanical principles. A more satisfactory *rationale* for heredity is also demanded.

Prof. du Bois-Reymond dismisses in a few words the arguments of Driesch and Rindfleisch (1888–93). In regard to Bunge ("Lehrbuch der physiol. Chemie," 1887), he points out that the "activity behind which lies the mystery of life" is only static equilibrium of the organism, dependent on integrating stimuli, and reducible to a physical equation. In fact, it is metabolism, maintained by chemical processes, which convert potential into kinetic energy. We have here the *πρῶτον ψεῦδος* of the older vitalism, for it matters little whether we deal with the comparatively simple problem of fifty years back, or, with Driesch and Bunge, search into the cell and its atoms, or their yet unknown final particles. Impassable, indeed, are the limits of our knowledge, but let us confine our *ignorabimus* to its proper frontier.

To the first contention of Neo-vitalism, du Bois-Reymond opposes the molecular theory with its infinitesimal particles of matter; for the last, he refers us to the current controversy between Weismann and Herbert Spencer. There is, doubtless, room for criticism of the Darwinian theory. For instance, natural selection fails to account for the appearance of organs such as the poison-fangs of snakes or the electric organs of fishes, which are useless in the struggle for existence until fully developed. But if Darwinism were fore-doomed, and exposed, in the words of Herr Driesch, as "a cheap and specious deception," it is improbable that Neo-Vitalism would reap any benefit. There may be still another solution to the problem.

Now, as before, we stand in face of the unsolved riddle, Origin of Being, with all the wondrous chain and intricacies of development. Yet as an alternative to supernaturalism, we can conceive one primordial act of creation whereby the germ of life inherent in matter could develop by its intrinsic laws into the brain of a Newton. Thus, with no day of creation the whole order of nature would evolve mechanically, without intervention of Old or New Vitalism.

And so we return upon the ideas of Leibnitz, save that Materialism replaces Supernaturalism, inasmuch as we may conceive that infinite matter, with its qualities as we know them, has been circling in infinite space from all eternity.

Frances A. Welby.

SCIENCE IN THE MAGAZINES.

PROF. A. W. RÜCKER contributes to the *Fortnightly* a brief sketch of the work of von Helmholtz. Our readers are familiar with the investigations carried out by this eminent physicist; nevertheless, the two concluding paragraphs of Prof. Rücker's article sums up the chief of them so admirab y as to be worth quoting here.

"He was one of the first to grasp the principle of the Conservation of Energy. He struck independently, and at a critical moment, a powerful blow in its defence. He penetrated further than any before him into the mystery of the mechanism which connects us with external nature through the eye and the ear. He discovered the fundamental properties of vortex motion in a perfect liquid, which have since not only been applied in the explanation of all sorts of physical phenomena, of ripple marks in the sand, and of cirrus clouds in the air, but have been the bases of some of the most advanced and pregnant speculations as to the constitution of matter and of the luminiferous ether itself.

"These scientific achievements are not, perhaps, of the type which most easily commands general attention. They have not been utilised in theological warfare; they have not revolutionised the daily business of the world. It will, however, be universally admitted that such tests do not supply a real measure of the greatness of a student of nature. That must finally be appraised by his power of detecting beneath the complication of things as they seem, something of the order which rules things as they are. Judged by this standard, few names will take a higher place than that of Hermann von Helmholtz."

In the same magazine Sir Robert Ball discusses the possibility of life in other worlds—a subject that has a curious fascination for the unscientific, but upon which the author throws the light of modern scientific knowledge. "No reasonable person will," he thinks, "doubt that the tendency of modern research has been in favour of the supposition that there may be life on some of the other globes. But the character of each organism has to be fitted so exactly to its environment that it seems in the highest degree unlikely that any organism we know here could live on any other globe elsewhere. We cannot conjecture what the organism must be which would be adapted for residence in Venus or Mars, nor does any line of research at present known to us hold out the hope of more definite knowledge." The verdict thus appears to be "possible, but not probable," and the subject therefore stands where it did.

Mr. R. S. Gundry contributes to the same magazine an article on Corea, China, and Japan; and Mr. A. H. Savage-Landor one on Japanese people and customs; while Mr. G. Lindsay describes his rambles in Norsk Finmarken.

Prof. N. S. Shaler contributes to *Scribner* an interesting paper on "The Horse," the text being illustrated with pictures by Delort. He does not speak very highly of the animal's intelligence. In his words: "The mental peculiarities of the horse are much less characteristic than its physical. It is, indeed, the common opinion, among those who do not know the animal well, that it is endowed with much sagacity, but no experienced and careful observer is likely to maintain this opinion. All such students find the intelligence of the horse to be very limited. Although some part of this mental defect in the horse, causing its actions to be widely contrasted with those of the dog, may be due to a lack of deliberate training and to breeding with reference to intellectual accomplishment, we see by comparing the creature with the elephant, which practically has never been bred in captivity, that the equine mind is, from the point of view of rationality, very feeble." It is worth remark, however, that a good deal of misapprehension exists as to the intelligence of the elephant. According to the best authorities, though elephants are docile and obedient, their intellectual capacity is below that of most other Ungulates. Colonel H. G. Prout contributes his second article on "English Railroad Methods," giving a number of interesting facts respecting passenger and freight traffic, cost of construction, &c., in England and America.

Colonel A. G. Durand shows, in a paper in the *Contemporary*, that the southern region of the Eastern Hindu Kush is one full of interest. In the *Humanitarian*, St. George Mivart writes on "Heredity." A portrait of the author forms the frontispiece of the number Mr. Grant Allen continues his moorland idylls in the *English Illustrated*, his subject this month being house-martins.

Chambers's Journal contains its usual complement of chatty articles, among which may be mentioned "Feathered Architects," "The Infinity of Space," and "The Vanishing Eland." *Longman's Magazine* reprints an address, "How to Make the Most of Life," delivered by Sir B. W. Richardson before the Literary and Scientific Section of the Grindelwald Conference this year. The Rev. B. G. Johns writes on "The Injuries and Benefits of Insects" in the *Sunday Magazine*, and the Rev. T. R. R. Stebbing contributes an instructive article on certain crustacea to *Good Words*. The latter magazine also contains an article on tea, by Mrs. A. H. Green, and a well-written explanation of the laws of motion, by Emma Marie Caillard.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The examiners for the Burdett-Coutts Scholarship have reported that no candidate of sufficient merit has presented himself for examination. The Scholarship, therefore, has not been awarded this year.

There will be an election to a Geographical Studentship of the value of £100 at the end of Hilary Term, 1895. Candidates should send in their names to the Reader in Geography, 1 Bradmore Road, Oxford, before Wednesday, February 27, 1895.

The Savilian Professor of Astronomy, Prof. H. H. Turner, will lecture in the Schools on Thursday, November 8, on the subject of the Transit of Mercury on Saturday, November 10.

In a Convocation held on Tuesday, November 6, the degree of Master of Arts, by decree of the House, was conferred on Robert Warington, F.R.S., Sibthorpian Professor of Rural Economy.

CAMBRIDGE.—The Cavendish Laboratory Syndicate have presented a report on the pressing needs of the department of experimental physics. It appears that a large laboratory for elementary classes and an additional lecture room, together with certain accessory rooms, are urgently required. To erect and furnish these on a suitable scale would require some £10,000. As the University is unable to meet any such expense at present, it is proposed to put up part of the building at an expense of £4000, of which half can be provided from the accumulated fees of students working in the laboratory. The Financial Board think that £2000 more can be obtained from the Common University Fund. Mr. Fawcett, the architect, has prepared plans for the work, which are to be seen at the Cavendish Laboratory.

The Sedgwick Memorial Museum Syndicate state that the tenders for the building designed by Mr. T. G. Jackson, A.R.A., have been some £4500 in excess of the estimate based on the architect's calculations. They are reluctantly forced to the conclusion that the University cannot afford to supplement the Memorial Fund to the required extent, and they accordingly ask powers to reconsider the plan, or to substitute a new one for it.

At the annual election to Fellowships at St. John's College, on November 5, Mr. H. C. Pocklington was one of the successful candidates. He was bracketed Fourth Wrangler 1892, was placed in the first division of the first class with Mr. Cowell, the Senior Wrangler, in Part II. of the Tripos of 1893, and this year gained one of the Smith's Prizes, the other falling to Mr. Hough, also a scholar of St. John's. Mr. Pocklington presented a dissertation on the periods of the vibrations of a vortex-ring constituted by fluid circulating round a hollow core, in which the periods of the unsymmetrical vibrations are for the first time determined. The analysis also included a determination of the effect which an electric charge would produce on the vibrations and the stability of a vortex atom in a rotational æther. In a minor investigation, which will appear in the next number of the *Proceedings* of the Cambridge Philosophical Society, the forms assumed by two parallel cylindrical hollow vortices moving steadily through fluid, and the character of the surrounding motion, are investigated in detail.

Mr. S. Sandars has bequeathed to the University £2000 for the endowment of a Reader in "Bibliography, palæography, typography, bookbinding, book-illustration, and the science of books and manuscripts."

As the result of the prolonged discussion on post-graduate study in the University, the Council of the Senate have sanctioned a grace for the appointment of a syndicate to consider (1) the best means of giving further help and encouragement to persons who desire to pursue courses of advanced study or research within the University; (2) what classes of students should be admitted to such courses; and (3) what academic recognition, whether by degrees or otherwise, should be given to such students, and on what conditions.

Mr. Herman, of Trinity College, has been appointed Chairman of Examiners for the Mathematical Tripos, Part I.

Dr. Forsyth, F.R.S., Sir R. S. Ball, F.R.S., R. T. Glazebrook, F.R.S., and Prof. G. B. Mathews, have been appointed Examiners for Part. II. of the Mathematical Tripos.

Prof. Ewing, F.R.S., Prof. Osborne Reynolds, F.R.S., and W. N. Shaw, F.R.S., have been appointed Examiners for the Mechanical Sciences Tripos.

DUBLIN.—The medals in Natural Science, given at Moderatorship, have been awarded as follows:—Gold medals to R. A. Rossiter and T. B. Jobson; silver medal to C. W. Orpen. The Professor of Botany's prizes for practical work on the Gymnosperms, to be accompanied by sections and drawings, have been given to T. B. Jobson, for work on the anatomy of the young stem of *Ginkgo biloba* and on the reproductive organs of *Taxus baccata;* and to R. A. Rossiter, for work on the floral development of *Thuja plicata* and *Larix Europea.*

Lectures on the Experimental and Natural Sciences for Michaelmas Term commenced on November 2. Prof. Reynolds lectures on Inorganic Chemistry, Prof. Fitzgerald on Heat, Prof. Sollas on Mineralogy and Physical Geology. Prof. Mackintosh lectures on Zoology, and gives demonstrations on Comparative Anatomy. Prof. Wright lectures on Algæ and Fungi, and gives a series of demonstrations on the Vascular Cryptogams. The assistant to the Professor of Botany, Mr. H. Dixon, gives a course of Laboratory instruction on vegetable cells and tissues.

The special courses in Natural Science for 1895 are in Geology, the Cambrian Period; in Zoology, the Invertebrate Heart; in Botany, the Natural Orders, Cruciferæ and Papilionaceæ.

The Anthropological Laboratory has reopened for the session 1894–95. Dr. C. R. Browne will, under the direction of Prof. D. Cunningham, give, on three days in each week during Term, demonstrations on Anthropological Methods. These will be open to all students.

Assisted by a grant from the Royal Irish Academy, Dr. C. R. Browne visited, during the long vacation, the district of North Erris, in the county of Mayo, believed to be one of the most primitive regions in Ireland. The anthropological results of this visit will in due course be laid before the Irish Academy.

The Dublin University Experimental Science Association held its first meeting for its eighteenth session on the 6th inst. Prof. Sollas delivered the opening address, in which he treated of "Geological Time."

FROM a Return made to the Department of Science and Art, and published last week, it appears that the total amount spent on technical education during the year 1892–93, in England, Wales, and Scotland, was £529,718, and that the estimated total amount allocated to technical education for the year 1893–94 was £696,328. Forty-one out of the forty-nine county councils in England are applying the whole of the residue received under the Local Taxation (Customs and Excise) Act to technical education, and eight a part of it to the same purpose. Of the councils of the sixty-one county boroughs, fifty-three are devoting the whole of the residue to technical education, and seven a part of it. The thirteen county councils and the three county boroughs in Wales and Monmouth are not only devoting the whole of the residue to intermediate and technical education, but six of them are also levying a rate, or making grants out of the rates, for the same purpose. In the case of Scotland, twenty-three out of the thirty-three county councils are applying the available funds to technical education, and seven a part. Of the 194 burghs and police burghs, however, 122 are applying the whole to the relief of rates.

THE Technical School Committee of the Birmingham Corporation have appointed Dr. W. E. Sumpner, of the Battersea Polytechnic School, from among seventy-five candidates, as Principal of the new local Technical School. The salary is £500 per annum.

THE extensive buildings that have been lately erected as an addition to the medical school at the Owens College, Manchester, were formally opened by the Duke of Devonshire, the President of the institution, on Tuesday.

SCIENTIFIC SERIALS

American Meteorological Journal, October.—The meteorological services of South America, by A. L. Rotch. In the Argentine Republic there are now five stations of the first order, forty of the second order, and one hundred rain stations. The first of the *Annales* was published in 1878, and dealt with the climate of Buenos Ayres from observations since 1801. In Uruguay there is one observatory of the first order, at Villa Colon, near Montevideo, and in 1890 a Meteorological Society was established, and publishes a monthly review. In Brazil, observations were made at Rio de Janeiro, since 1825, but no record of them is to be found until 1844; from this time summaries have been regularly published. A Central Meteorological Department was established in 1888 in connection with the bureau of the Navy, but the climatological service has not yet been organised.—The forecasting of ocean storms, &c., by W. Allingham. This paper was prepared for the International Meteorological Congress held at Chicago in August last. It deals more particularly with the storms of the North Atlantic, and the author shows that at present any attempt to forecast them from America is not very successful. Nevertheless, the Meteorological Office of Paris continues to receive and publish daily reports from the United States and Canada, as well as from steamers arriving at American ports from the Atlantic.—Sun-spots and Auroras, by Prof. H. A. Hazen. The author has laid down curves of all the sun-spots measured on the Greenwich and India photographs from 1881 to 1888, and also the auroral numbers recorded in the United States, and shows that auroras and sun-spots are not concomitant or coincident phenomena. For the purpose of inquiring into the annual range, the auroras and sun-spots for twenty-three years have been summed for months. There is a remarkable correspondence in these results; both phenomena show a maximum in April, and the second maximum occurs in September for auroras, and in October for sun-spots. Prof. Hazen considers that the investigation of sun-spots and auroras is the most promising line that can be taken in a study of the possible effects from some cosmical force upon our atmosphere.

Bulletin of the American Mathematical Society, second series, vol. i. No. 1 (October 1894).—This is a continuation of the *Bulletin* of the New York Society. The title of the Society having been changed, as previously announced, of necessity the title of the *Bulletin* is also changed. An article on the "Summer meeting of the American Mathematical Society" gives an account of the doings, and abstracts of the papers read, at the August meeting in Brooklyn, N.Y., of the American Association for the Advancement of Science. The co-operation of the two Associations resulted in a successful gathering for the younger body.—Other articles in this number are on the connection between binary quartics and elliptic functions, by Prof. E. Study. This is an abstract of a paper which will appear in the *American Journal of Mathematics*. It shows how a certain group of rational and irrational co-variants of a binary quartic can be expressed as one-valued functions of one or two parameters, thus filling up a number of lacunæ contained in former presentations of the subject.—Reduction of the resultant of a binary quadric and n-ic by virtue of its semi-combinant property, by Prof. H. S. White. The author discusses the partial problem solved by Clebsch, viz. to write in symbolic form the resultant of a binary quadric and a binary quantic of arbitrary order n. The method employed is novel, and illustrates the utility of the theory of conjugate forms.—Next a list of astronomical papers read at the American Association meeting (see *supra*), is given, and short abstracts supplied. Notes and new publications complete this number.

American Journal of Mathematics, vol. xvi. No. 4 (Baltimore, October 1894).—"Sur la transformation des courbes algébriques," by E. Goursat (pp. 291–298), discusses two generalisations of a theorem demonstrated by Lüroth (*Math. Annal.* ix. p. 163). The rest of the number (pp. 299–396) is taken up by a masterly memoir on isotropic elastic solids of nearly spherical form, by C. Chree. It is preceded by a full table of contents, and has 320 equations. The author remarks that the investigation of a solution of the elastic solid equations for the equilibrium or motion of homogeneous isotropic material enclosed by the simplest of all surfaces, the spherical, presents no small difficulty. For even a slight departure from the spherical form the increase of difficulty is so considerable that, so far as I know, the only problem of the class successfully treated hitherto is that of a nearly spherical solid exposed to gravitational force, but free of all surface force. In the case considered by Mr. Chree, surface forces appear as well as bodily forces, so that the problem is much more general than that previously treated. His method is novel, and the memoir closes with some speculations as to the action of the sun on the earth.

Bulletin de la l'Académie Royale de Belgique, No. 8.—Note on the subject of a recent communication from M. Ch. Lagrange, by M. F. Folie. The author claims to have been the first to announce that the theoretical period of initial nutation would be found too short owing to the internal fluidity of the globe, and that the best method for observing this nutation would be that of observations at intervals of twelve hours. He also stated that the variations of latitude would be equal and of opposite sign on two opposite meridians in the same hemisphere, which was borne out by observations in Europe and Honolulu. His hypothesis explaining the annual variations is capable of explaining and estimating the systematic differences between the catalogues of Greenwich and the Cape, given by Downing, and by the diurnal nutation, the differences between Paris, Pulkowa, and Washington, and between Melbourne and the Cape.—On the origin of the dicrotism and the undulations of the systolic plateau of arterial pulsation, by Victor Willem. This work was undertaken in order to decide whether any of the pulsations shown by the sphygmograph and the recorders of arterial pressure have a peripheral origin, or whether they all start from the heart and its neighbourhood. Experiments upon the carotid and crural arteries of dogs show that the latter alternative is true. The author further studied the influence of various injections upon the pulsation.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, October 17.—Henry John Elwes, President, in the chair.—Dr. H. G. Breyer, of Prætoria, Transvaal, South Africa, was elected a Fellow of the Society. Mr. G. C. Champion read a letter, dated August 15 last, from Mr. J. Y. Johnson, of Funchal, Madeira, on the subject of a recent visitation of locusts to the island, and exhibited specimens. Mr. Johnson mentioned that Darwin, in his "Origin of Species," recorded that in November 1844, dense swarms of locusts visited Madeira. He said that since then, until August last, these insects had not visited the island. Mr. Champion remarked that the species was *Decticus albifrons*, Fabr., not a true migatory locust. Mr. Champion also exhibited specimens of *Anthaxia nitidula*, *Velleius dilatatus* and *Athous rhombeus*, taken by himself in the New Forest during the past summer.—Mr. H. Goss read a letter received from Captain Montgomery, J.P., of Mid-Ilovo, Natal, reporting vast flights of locusts there, extending over three miles in length, on August 31 last, and exhibited a specimen of the locust, a species of *Acridium*. Captain Montgomery stated that, as a rule, his district, like most of Natal, was free from the pest, but that an exceptional invasion had occurred in 1850.—Mr. J. W. Tutt exhibited four typical specimens of *Emydia cribrum* from the New Forest, and, for comparison, four specimens of the variety, *candida*, of the same species, taken at an elevation of 4000 feet, near Courmayeur, on the Italian side of Mont Blanc. He stated that he had also met with this form in the Cogne Valley, at an elevation of from 6000 to 8000 feet.—Mr. R. Adkin exhibited a specimen of *Erebia æthiops*, in which the left fore wing was much bleached, taken in August last, near Carnforth. Mr. Adkin also exhibited a series of *Acronycta rumicis* from Co. Cork, Ireland, including light and black forms, with examples from the Scilly Isles, Isle of Man, and North of Scotland for comparison.—Mr. Elwes exhibited a series of *Chionobas alberta* ♂ ♀, *Chionobas uhleri*, var. *varuna*, and *Erebia discoidalis*, from Calgary, Alberta, N.W. Canada, which had been collected in May last, by Mr. Woolley-Dod. He said that the validity of *C. alberta*, which had been questioned by Mr. W. H. Edwards, was fully established by these specimens.—Prof. E. B. Poulton, F.R.S., gave an account of the changes which he had recently made at Oxford in the arrangement of the Hope Collections in the Department of Zoology, and as to the rooms now available for students working at these collections.—Mr. G. T. Bethune-Baker communicated a paper, entitled "Descriptions of the Pyralidæ, Crambidæ, and Phycidæ, collected by the late T. Vernon-Wollaston in Madeira."

PARIS.

Academy of Sciences, October 29.—M. Lœwy in the chair.—Experimental verifications of the theory of weirs, with either adherent or partly submerged water-sheet, with regard to the pressures, by M. J. Boussinesq.—On the existence in plants of principles capable of condensation with production of carbonic acid, by MM. Berthelot and G. André. Plant-leaves were dried at 110°, reduced to powder, and then heated on an oil-bath, at 120°–130°, with 12 per cent. hydrochloric acid. The work was carried out in an atmosphere of hydrogen. It resulted in a slow evolution of carbon dioxide. This may be accounted for on the hypothesis that the contained carbohydrates have a ketonic constitution. Experiments on the simple carbohydrates are in progress.—On the movements which certain animals make in order to fall on their feet, when precipitated from a height, by M. Marey. Successive instantaneous photographs, taken in two planes, are given of a cat in the act of falling. The necessary movements are accomplished by the animal rotating the forepart of its body when drawn in, so that its moment of inertia is small as compared with that of the extended hind-quarters, and by this movement being repeated by the latter when drawn in and the fore-part extended.—A note concerning the above communication, by M. Guyon. It is shown that the rotation of the animal is not contrary to received laws.—Observations on the principle of areas, by M. Máurice Lévy.—Reduction of the equation of continuity in hydraulics to the form $\frac{d\rho}{dt}+v_1\frac{d\rho}{ds}+\rho\frac{dv_1}{ds}-2\rho v_1\frac{\delta' a}{ds''}=0$. An abstract of a memoir by M. P. E. Touche.—The first volume of a work by M. G. Hinrichs, "On the Mechanics of Atoms," gives a discussion of atomic weights and methods used in their determination, and treats of the question of the unity of matter.—On the problems of dynamics of which the differential equations admit a continuous group, by M. P. Staeckel.—On the differentiation of trigonometric series, by M. Matyas Lerch.—On the constitution of the electric arc, by M. L. Thomas. The arc between two carbons containing metallic salts consists of a nucleus surrounded by an envelope; in the former are found the substances giving band spectra, hydrocarbons or carbon vapour and cyanogen, in the envelope metallic vapours from the dissociated salts pass from the positive to the negative pole, and there burn in the oxygen of the air, producing the metallic line spectra characteristic of this region.—Relation between the maximum vapour pressures of water, ice, and a saline solution at the freezing-point of this solution, by M. A. Ponsot.—On the gaseous products given off by wood charcoal when heated to a high temperature out of contact of air, by M. Dosmond.—On the transformation temperatures of irons and steels, by M. Georges Charpy.—Kermésite, by M. H. Baubigny.—On the superposition of optical effects of several asymmetric carbon atoms in the same active molecule, by MM. Ph. A. Guye and M. Gautier. In a molecule containing several asymmetric carbon atoms, each of them acts as if all the remainder of the molecule were inactive. The optical effects of several asymmetric carbon atoms in the same molecule are algebraically added to give the optical activity of the molecule.—On the saturated hydrocarbons with active amyl radicals, by Mdlle. Ida Welt.—On the estimation of alcohol in essential oils, by MM. Charles Fabre, Garrigou, and Surre.—On the existence of *cellules en paniers* in the *acinus* and excretory conduits of the mammary gland, by M. E. Lacroix.—Observations on a note by MM. Prillieux and Delacroix.—On the *gommose bacillaire* of vines, by M. L. Daille.—Culture of a fungus (*Collybia velutipes*) growing on wood, by MM, Costantin and Matruchot.—On the disease "Rouge" in the Paris nurseries and plantations, by M. Louis Mangin.—On the relations of the basalt and phonolite of the Suc d'Araules (Haute-Loire), by M. Ferdinand Gonnard.—On the geology of French Congo, by M. Maurice Barrat.—On several quaternary grottos of the Dordogne, and on some megalithic monuments of Orne and La Manche, by M. Émile Rivière.

NEW SOUTH WALES.

Royal Society, June 6.—C. Moore in the chair.—The following papers were read:—Notes on some minerals and mineral localities in the northern districts of New South Wales, by D. A. Porter.—On the magnetic susceptibilities of specimens of Australian basalts, by Prof. A. W. Rücker, F.R.S.—On boleite, nantokite, kerargyrite, and cuprite, from Broken Hill, by Prof. Liversidge, F.R.S.—From number to quaternion, by C. Fleuri.—New orbit of the double star β 416 = Scorpii 185, by Prof. S. Glasenapp.—On the value of gravity at the Sydney Observatory, by E. F. J. Love.—Preliminary notes on the pharmacology of *carissa ovata*, var. *stolonifera*, Bail, by Dr. T. L. Bancroft.—On the almandine garnets from the Hawkesbury sandstone at Sydney, by H. G. Smith.—On a natural mineral spring at Bungonia, by Rev. J. Milne Curran.

July 4.—Prof. Threlfall, President, in the chair.—The following papers were read:—On a transparent star-chart: a convenience for observers, by H. C. Russell, F.R.S.—Aboriginal Bora held at Gundabloui in 1894, by R. H. Mathews.—Observations and orbit elements of comet Gale 1894, by John Tebbutt.—On the structure and composition of some Australian basalts, by Rev. J. Milne Curran.

August 1.—Prof. Threlfall, President, in the chair.—The following papers were read:—On garbage destructors, by Prof. Warren and Dr. Ashburton Thompson.—The geology of lime-kilns, Bathurst district, by W. J. C. Ross.—The territorial divisions of New South Wales into counties, by W. D. Campbell.—On the timbers of New South Wales, by J. V. De Coque.—On the Aboriginal rock carvings and paintings in New South Wales, by R. H. Mathews.—The Society's bronze medal and money prize of £25 were presented to each of the two last-named gentlemen for their papers.

September 5.—Prof. Threlfall, President in the chair.—The following papers were read:—Some stone implements used by the Aborigines of New South Wales, by R. H. Mathews.—Recent researches in the testing of cement, by W. S. de Lisle Roberts.—A comparison of the languages of Ponape and Hawaii, by the late Rev. E. T. Doane, with additional notes and illustrations by Sidney H. Ray.—Preliminary note on the structure of gold nuggets, by Prof. Liversidge, F.R.S. Gold nuggets on being cut through or sliced and polished, and then etched by chlorine water, were found to exhibit well-marked crystalline structure closely resembling the Widmanstatt figures shown by most metallic meteorites, except that in the nuggets the crystals are more or less square in section and show faces which evidently belong to the octahedron and cube. On heating the nuggets in a bunsen burner, blebs or blisters form, on both the polished and unpolished surfaces, and on still more strongly heating, these, in some cases, burst with sharp reports, and pieces of gold are projected with considerable violence. As no explosions have been observed on dissolving or eating away the crusts of these blisters by chlorine water, it would appear that the blebs are probably due to the vaporisation of some liquid or solid substance. As soon as a fresh supply of nuggets is obtained, experiments will be proceeded with to ascertain definitely whether gold nuggets contain occluded gases, or liquids or solids which are vaporisable. In slicing some nuggets, scattered granules of quartz were met with inside, although quite invisible outside, and at first it was thought that the explosions might be due to the quartz; but the gas, in some cases, continued to issue from the burst bleb (where the aperture formed was small) and forced the bunsen flame out into lateral jets, just as if urged by a blow-pipe.

Linnean Society, September 26.—Prof. David, President, in the chair.—On the correct habitat of *Patella kermadecenis*, Pilsbry (=*P. Pilsbryi*, Braz.), by John Brazier. The author expressed the opinion that this is the species referred to in Mr. Percy Smith's pamphlet, "The Kermadec Islands: their Capabilities and Extent" (Wellington, 1887), which states that on Macauley Island there occur "large limpets (as big as small saucers, and good eating)."—On a *Trochus* from Port Jackson, and new varieties of *Bulimus miltocheilus*, Reeve, from the Solomon Islands, by John Brazier. Under the name of *Trochus Adamsi*, n.sp., was re-described a Port Jackson mollusc, the original specific name of which (*T. comptus*, A. Ad.) is preoccupied for a species named by Phillipi. Dr. Fischer also confounded *T. comptus*, A. Ad., with the New Caledonian *T. Poupineli*, Montr., which is a distinct species. Three new varieties of *Bulimus miltocheilus*, Reeve, were also described.—Observations on *Dendrolagus bennettianus*, De Vis, by Edgar R. Waite. The author described the species from material recently obtained from the Bloomfield River, Queensland. He was of opinion that in respect of both external and anatomical characters it is a well-marked species.

AMSTERDAM.

Royal Academy of Sciences, September 29.—Prof. Van de Sande Bakhuyzen in the chair.—Mr. Beyerinck discussed the reduction of sulphates by a specific sulphide ferment. This subject bears on two questions of general bacteriology, *i.e.* (1) the production of sulphuretted hydrogen, and (2) the power of reduction. Bacteria may produce H_2S in four different ways: Firstly, from sulphur, this being dissolved, by the excretion of ammonia, amines or alkaloids forming sulphides, which are decomposed by carbonic acid; secondly, from proteids containing sulphur, well known in cases of putrefaction; thirdly, from sulphites and thiosulphates (the latter of these substances being decomposed into sulphites and sulphur, and the sulphites acted on as in the first case); fourthly, by the reduction of sulphates. From the common reducing bacteria which turn nitrates into nitrites, and these into ammonia salts, which produce from litmus, indigo-blue, methylen-blue, &c., the corresponding leucoids, none has the power to attack sulphates. This is done by a specific ferment, a very small *spirillum*, which is perfectly anærobic, and which is common in the black mud of polluted waters, as also in these waters themselves. It grows with very small quantities of organic nutriment, as malates, peptone, sugar, and phosphates added to common water, rendered alkaline by sodium carbonate. Temperatures from 25° to 30° are the best for reduction. For the determination of the H_2S the iodometric method can be used. Common water with the addition of $\frac{1}{10}$ per cent. sodium malate, $\frac{1}{10}$ per cent. asparagin, $\frac{1}{10}$ per cent. potassium phosphate, and $\frac{1}{2}$ per cent. sodium carbonate, infected with mud containing the ferment, and secluded from the air, and with forty-five milligrammes SO_3 per litre, was in three days quite free from this substance, containing nearly 10·2 milligr. H_2S, the cause of the deficit (twenty-one milligr. SO_3, not transformed into H_2S) being not yet quite clear. Mohr's salt (ferrous ammonium sulphate) is very well adapted for reduction experiments, the smallest trace of reduction being indicated by the formation of black FeS. The spirillum has been named *Spirillum desulfuricans*. It seems to be of geological importance, inasmuch as the deep ground water of the province of South Holland is quite free from sulphuric acid, which, being abundant on the surface, is apparently reduced by the sulphide ferment, and rendered insoluble as FeS and FeS_2.—On Kerr's magneto-optic phenomenon, by C. H. Wind. The author supposes that, in a metal placed in a magnetic field, both the conduction and the displacement current give rise to a *Hall*-effect, the intensity coefficient being different in the two cases. In this way the discrepancy, which exists between the experimental results, and the theory of Lorentz and Van Loghem, may be removed.—Prof. Kamerlingh Onnes read a memoir, in which Dr. Kuenen gave a graphical representation of the condensation of a mixture of two substances with π and ι taken as co-ordinates. His conclusions are contradictory to those of Duhem, but in accordance with the theory of Van der Waals and his own experiments. All mixtures of two substances must show retrograde condensation.—Prof. Onnes also communicated the results of an investigation, by Dr. Borgesius, on the molecular refraction and dispersion of some salts in solution, made with an interferential refractometer especially constructed for this purpose, and giving the small differences of refraction of two fluids by a single reading of verniers and counting of striæ.

THURSDAY, NOVEMBER 15, 1894.

HISTORICAL EXPOSITION OF MECHANICS.

The Science of Mechanics: a Critical and Historical Exposition of its Principles. By Dr. Ernst Mach, Professor of Physics in the University of Prague. Translated from the second German edition by Thomas J. McCormack. (Chicago: The Open Court Publishing Co. London: Watts and Co., 1893.)

THE appearance of a translation into English of this remarkable book should serve to revivify in this country the somewhat stagnating treatment of its subject, and should call up the thoughts which puzzle us when we think of them, and that is not sufficiently often.

Prof. Mach isa striking instance of the combination of great mathematical knowledge with experimental skill, as exemplified not only by the elegant illustrations of mechanical principles which abound in this treatise, but also from his brilliant experiments on the photography of bullets, which have been recently elaborated and simplified by Mr. C. V. Boys.

The appearance of the first edition, in 1883, is stated in the preface of the second edition, to have stimulated the production of treatises by Wohlwill, Streintz, Lang e, Epstein, Müller, Popper, Helm, Planck, Poske, and others, discussing theories of cognition in connection with Mechanics; but it is curious that Maxwell's little tract on "Matter and Motion," of 1879, a veritable master-piece on this subject, should appear to be unknown to the author, although mentioned in the translator's foot-notes.

The present volume is not a treatise upon the application of the principles of mechanics, to quote from the preface. Its aim is to clear up ideas, expose the real significance of the matter, and get rid of metaphysical obscurities. Mechanics is treated not as a branch of mathematics, but as one of the physical sciences; and the reader's interest is invited to know how the principles of mechanics have been ascertained, from what sources they take their origin, and to what extent they may be regarded as permanent acquisitions. All this, the positive and physical essence of mechanics, which makes its chief and high interest for a student of nature, is in existing treatises completely buried and concealed beneath a mass of technical considerations.

The gist and kernel of mechanical ideas has in almost every case grown up in the investigation of very simple and special cases of mechanical processes; and the analysis of the history of the discussions concerning these cases must ever remain the method at once the most effective and the most natural for laying this gist and kernel bare. Indeed, it is not too much to say that it is the only way in which a real comprehension of the general upshot of mechanics is to be attained.

Acting upon the plan laid down in the citations above, the author treats his subject from the historical order of development, and begins with an Introduction of general remarks, illustrated by an Egyptian representation of the mechanical arts, and by a quotation from Vitruvius.

Chapter i., on the Development of the Principles of Statics and Hydrostatics, follows closely the historical subject-matter given by Lagrange in the first section of his "Mécanique analytique"; but Prof. Mach's treatment has the very great superiority of being profusely illustrated by elegant diagrams, while Lagrange made a point of banishing figures entirely from the "Mécanique analytique."

Lagrange thus appears as a supporter of the ancient tradition that Rational and Practical Mechanics were to be considered as in a measure opposed to each other, as Newton observes in his preface of the "Principia"; the latter being an inferior branch of study, to be cultivated only for the sake of gain or some other material advantage.

To quote from Rankine's Preliminary Dissertation, prefixed to his "Applied Mechanics":—

"Archytas of Tarentum might illustrate the truths of Geometry by mechanical contrivances; his methods were regarded by his pupil Plato as a lowering of the dignity of science. Archimedes, to the character of the first geometer and arithmetician of his day, might add that of the first mechanician and physicist—he might, by his unaided strength acting through suitable machinery, move a loaded ship on dry land—he might contrive and execute deadly engines of war, of which even the Roman soldiers stood in dread—he might, with an art afterwards regarded as fabulous till it was revived by Buffon, burn fleets with the concentrated sunbeams; but that mechanical knowledge and that practical skill, which in our eyes render that great man so illustrious, were by men of learning, his contemporaries and successors, regarded as accomplishments of an inferior order, to which the philosopher, from the height of geometrical abstraction, condescended with a view to the service of the State."

We have only to study the progress of the essentially modern science of Electricity to recognise the eloquent truth of Rankine's words, in inveighing against the mediæval and ancient fallacy that there is a *double system of natural laws*, one theoretical, geometrical, rational, discoverable by contemplation, applicable to celestial, ætherial, indestructible bodies, and being an object of the noble and liberal arts; the other practical, mechanical, empirical, discoverable by experience, applicable to terrestrial, gross, destructible bodies, and being an object of what were once called the vulgar and sordid arts.

Possessed with these prejudices, the scholar of ancient and mediæval times, and even of the present day, was occupied in developing and magnifying the numerous errors, and in perverting and obscuring the much more numerous truths which are to be found in the writings of Aristotle; so that it is not surprising that the notion arose of scientific men being unfit for the business of life, and that various facetious anecdotes were contrived illustrative of this notion, anecdotes which have been handed down from age to age, and applied with little variation to the eminent philosophers of every time.

Returning to chapter i. of Prof. Mach's treatise, we find that the Principle of the Lever, employed in the writings of Archimedes, is the real foundation of the Science of Statics, and not the Parallelogram of Forces, as is generally taught; this theorem, although sketched out by Stevinus of Bruges, was first fully enunciated by Varignon and Newton, about 1687. In fact, the modern treatment of Statics is almost entirely due to Varignon.

Prof. Mach examines with the acumen of a metaphysician the weak points of a demonstration; it is a pity then that he seems unacquainted with Duchayla's proof of the Parallelogram of Forces, which is unfortunately so popular with writers on mechanics in this country, as he would have revelled in pointing out the weakness of a logic which prides itself above all things on its rigour.

The Principle of Virtual Velocities, employed as fundamental by Lagrange in his "Mécanique analytique" in preference to the principle of the Parallelogram of Forces, was enunciated very clearly by Stevinus in its application to systems of pulleys; and here we are compelled to call attention to a flaw in Fig. 39, *c*, the only one that we have met in the course of the work; the system cannot possibly be in equilibrium with the central portion of the thread askew, as drawn in the diagram.

The Principle of Virtual Velocities is important in the historical development of Mechanics as the first sketch and shadowing forth of the modern Principle of the Conservation of Energy; but it is unfortunate that the name should still survive, as it is confusing and meaningless. Prof. Mittag Leffler was eloquent at the meeting of the British Association at Oxford in his denunciation of the habit of attaching to theorems certain names of individuals, real or quasi discoverers; and he might have quoted the Principle of Virtual Velocities as an instance of the disadvantage of inventing a descriptive title of too great generality to a newly discovered theorem.

Lagrange has attempted an experimental verification of the Principle of Virtual Velocities, and it is a tradition that an apparatus was constructed on these indications by a former professor of mathematics at Cambridge. It is probable that the description of this demonstration and of the apparatus to be found in Todhunter's *Analytical Statics* was purposely ironical; and that, in popular language, Todhunter wrote this with his tongue in his cheek, knowing the story of the sceptical student who had tried the experiment himself.

The demonstration amounts to proving that a certain weight is no more likely to rise than to fall, and therefore (here Todhunter says he follows Lagrange's words very closely) the weight should remain stationary. The student, however, found that the weight did not remain stationary, and wanted to know why; the professor told him in confidence that it was prudent to make use of an invisible pin to keep the weight in order.

This is not the only case in which it is desirable for the professor to keep a card up his sleeve, as the saying is; in the Foucault experiment of the pendulum which shows the rotation of the Earth, the slightest current of air will destroy and reverse the desired motion; so that it is advisable in showing the experiment to have an elastic ball concealed in the palm of the hand, which can send a slight current of air on the bob of the pendulum, and thus accelerate the initial precession of the plane of the vibration so as to gratify the eyes of the audience and diminish their impatience at the slowness of the motion; afterwards the motion can be checked so that the total advance is made to agree with the theoretical result. Very undignified and dishonest, some will say; but the experiment is otherwise bound to fail from its delicacy when shown to a large audience, except under the most favourable conditions.

While Statics, both as a Science and an Art, can be traced back through Archimedes and the existing monuments of the Egyptians, Greeks, Romans, and of mediæval architects, the Principles of Dynamics, discussed in chapter ii., were first laid down clearly by Galileo; and the great fallacy to be destroyed before any real advance could be made was that of the Aristotelians, who maintained that heavy bodies fall faster than light ones, because the upper parts weigh down on the under parts and accelerate their descent. But in that case, retorted Galileo, a small body tied to a larger body, must, if it possesses *in se* the property of less rapid descent, retard the larger; *ergo* a larger body falls more slowly than a smaller body.

The entire fundamental assumption is wrong, as Galileo says, because one portion of a falling body cannot by its weight under any circumstances press another portion; although, according to Wohlwill (Appendix I.), even Galileo himself only very gradually abandoned the Aristotelian conceptions.

But discarding all metaphysical argument, the Aristotelian fallacy was demolished once for all by the *experimentum crucis* carried out by Galileo, of letting bodies of different weight fall from the Leaning Tower of Pisa, when all were found to take the same time of descent; any slight discrepancies were afterwards accounted for by the resistance of the air.

A still more delicate experimental verification is to be found in the pendulum, as pointed out by Galileo; a plummet at the end of a thread has the same period of oscillation whatever be the weight or the material of the plummet.

The theory of the pendulum, when composed of a body of finite size, as required in a clock, was completed by Huygens in his *Horologium oscillatorium*, 1673, in which the mutual controlling influence of a number of separate plummets is investigated when the plummets are rigidly attached together; and thus for the first time the idea of a moment of inertia and of a centre of oscillation was introduced into Mechanics. In his further researches into the theory of the clock, Huygens was led to the discovery that isochronism for all amplitudes can be secured by making the plummet oscillate in a cycloid; and to do this practically he found that the thread must wrap and unwrap on an equal cycloid, and thereby he made the first step in the doctrine of evolutes and the theory of the circle of curvature.

Having demolished the Aristotelian fallacies on falling bodies, Galileo had still to determine the true laws; his first conjecture that the velocity grew uniformly with the distance, or that $v = gs$, having proved untenable, Galileo stumbled upon the true law that the velocity grows at a constant rate, or that $v = gt$.

The next step in the theory, to prove that in consequence $s = \frac{1}{2}gt^2$, was not an easy matter for Galileo, who sought in general an experimental proof of his theorems (as, for instance, his attempted quadrature of the cycloid by weighing it made in sheet lead); once this was established, however, it was comparatively an easy matter to demonstrate that the path of an unresisted projectile is a parabola, and to prove it experimentally by rolling a ball obliquely on an inclined table.

Galileo's difficulty was to measure lapse of time with exactitude, accurate clocks and watches not being in existence in his day; but he overcame this difficulty by a modification of his own invention of the ancient Clepsydra.

The laws of circular motion were next investigated by Huygens; and a combination of these laws with Kepler's Third Law, on the assumption that the planetary orbits round the Sun are circles, leads at once to the Law of Attraction varying inversely as the square of the distance.

This law, generalised into the Law of Universal Gravitation, became in Newton's powerful hands the foundation of his system of Natural Philosophy, in explaining not only the elliptic orbits of the planets in accordance with Kepler's first two Laws, but also the perturbations of these orbits as exemplified in the Lunar Theory, and the Theory of the Tides.

Prof. Mach suggests in Fig. 139 a very ingenious experimental illustration of the tides on a body in free space, like the Earth, as distinguished from the tides which would be produced if the Earth was fixed, by means of a small iron sphere covered with a solution of magnetic sulphate of iron; this can either revolve as the bob of a conical pendulum in true planetary style round the pole of a fixed magnet, representing the disturbing Sun or Moon; or it can hang suspended at rest at a small distance from the pole, and thus illustrate high water under the disturbing Sun or Moon, and low water at the antipodes when the Earth is supposed fixed. The discrimination of the two cases must be considered one of the most brilliant parts of the "Principia."

It is curious that Prof. Mach does not accept Newton's distinction between the relativity of motion of translation and the absoluteness of motion of rotation, illustrated experimentally by Newton by means of a revolving bucket of water suspended by a twisted rope ("Principia," Definition VIII. *Scholium*); and here we think he would have been interested in Maxwell's arguments on Rotation in § 104, *Matter and Motion.*

Maxwell proceeds to explain that it is possible, by means of observation and experiment on or inside the Earth alone (by Foucault's pendulum, for instance), to disprove Milton's assumption, that it is evidently all the same

"Whether the sun, predominant in heaven,
Rise on the earth, or earth rise on the sun;
He from the east his flaming road begin,
Or she from west her silent course advance;"

&c., although the geometrical configuration of the earth and the heavenly bodies, so far as is discoverable by astronomical observation, is the same on either assumption.

In the Translator's Preface we are told that "Mr. C. S. Pierce has rewritten § 8 in the chapter on Units and Measures, where the original was inapplicable in this country (America) and slightly out of date."

As might be anticipated, this means that we are now to change the name of the quantity formerly designated by the word *weight*, *poids*, *gewicht*, *pondus*, and to use the word *mass* instead.

But if a continental mathematician, Prof. Mach included, is asked to give a numerical definition of the mass of a body, he replies, if in French, "poids divisé par g"; so that if a body weighs p kilogrammes, its mass is $\frac{p}{g}$, and the unit of mass is thus g kilogrammes.

When the gravitation unit of force was in universal use, it was considered an abbreviation to write m for $\frac{p}{g}$, and to replace the gravitation measures of momentum and energy, $\frac{pv}{g}$ and $\frac{pv^2}{2g}$, by mv and $\frac{1}{2}mv^2$.

But when Gauss's absolute unit of force is employed, the absolute measures of momentum and energy are pv and $\frac{1}{2}pv^2$, and the abbreviation of m for $\frac{p}{g}$ is no longer required; or if the letter m is employed, then $p=m$ and not mg, as Mr. Pierce asserts; if the mass of a body is 10 kilogrammes, its weight in kg cannot be anything except 10 kilogrammes.

But if with absolute measures we retain the equation $p=mg$, and measure m in kilogrammes, then p, the *weight* or *poids*, is measured in one-gth parts of a kilogramme; this is contrary to all practice, and is absolutely forbidden by the laws on *Weights and Measures.*

With gravitation units the *weight* of a body is at once the numerical measure of the quantity of matter in the body (Newton's *quantitas materiæ*) and of its gravitation, or the force with which it tends to the Earth; if a body weighs p kilogrammes, it is attracted by the Earth with a force of p kilogrammes. The loose definition usually given that "the weight of a body is the force with which it is attracted by the Earth," is really no definition at all, but a mere description; it should at least be amended to "the weight of a body is the *number of units of force* with which the body is attracted by the Earth"; and it will be found that this definition is never employed except with the gravitation unit of force; so that this definition merely asserts in a roundabout way that the weight of a body is a measure of the quantity of matter, as measured out by weighing against pound or kilogramme weights.

It is incorrect to say that there are two systems of *measurement*, the *absolute* and the *gravitational* (p. 284). There is no practical method for the measurement of forces in absolute measure with any pretence to accuracy; the absolute system is merely a system for recording numerically the results of experiment; the measurements themselves are always made in gravitation measure, and afterwards converted into absolute measure by multiplying by the local value of g. There is thus no need for absolute units with our insular British F.P.S. (foot-pound-second) system; and Prof. James Thomson's *poundal*, although a convenient name, is of no practical or theoretical use.

In experiments at Washington, the Paris gravitation unit would not be employed, so that the statements on p. 286 do not tend to clear up the subject. What appears to be meant is that if a perfect spring balance could be constructed such that a kilogramme deflected it at Paris through 981 divisions, then when carried to Washington the deflection would fall to 980·1 divisions, and if carried to the Moon to about 164 divisions, but if carried to the surface of the Sun the deflection would rise to about 30,000 divisions, provided Newton's "Law of Universal

Gravitation" is correct; but the kilogramme weight remains the same throughout the universe.

But if a balance could be constructed with its fulcrum somewhere in the Azores, and the scale pans hanging over Paris and Washington, then 1 kilogramme at Paris would equilibrate 1·00092 kilogramme at Washington (p. 286).

It is sometimes asserted in our school-books on Mechanics that a pound weight, if carried to the surface of the Sun, would weigh about 30 pounds; but if a balance could be made to stretch between the surfaces of the Earth and of the Sun, then a pound weight at the Sun's end would be equilibrated by 30 pounds at our end; so that it is equally true to say that a pound weight on the Sun will weigh 30 pounds on the Earth.

Prof. Mach would perform a great service if he would extend his criticisms on the usage of the word *pondus* by Huygens, Leibnitz, Wallis, &c., to modern times, as great mystifications exist at the present day.

The C.G.S. system of units is explained by Mr. Pierce on p. 285. These units are much too minute except for recording delicate physical measurement. If Prof. Johnstone Stoney's amendment of the M.K.S. (metre-kilogramme-second) system had been adopted, we should have a system incorporating the joule, watt, volt, ohm, and ampère as units; it is not too late to make the change; the disadvantage that the density of water is 1000 in this system is more apparent than real.

Although the double system of natural laws mentioned by Rankine is now exploded, we still have a double system of instruction in mechanical text-books, one theoretical, geometrical, rational; the other practical, mechanical, empirical, discoverable by experience. It should be the object of modern science to break down the barriers between these two systems, and to treat the subject of mechanics from one point of view. Instead of this, the gap between the two systems seems to be an increasing one, insomuch that Prof. A. B. W. Kennedy, in his inaugural address to Section G of the British Association at Oxford, demanded for young engineers a course of instruction in mathematics entirely different to that imparted at present in our schools and colleges.

Some remarks at the end of Prof. Klein's Sixth "Evanston Colloquium" may be consulted as bearing on this question.

A careful study of Prof. Mach's work, and a treatment with more experimental illustration, on the lines laid down in the interesting diagrams of his Science of Mechanics, will do much to revivify theoretical Mechanical Science, as developed from the elements by rigorous logical treatment.

A. G. GREENHILL.

NEWTH'S INORGANIC CHEMISTRY.

A Text-book of Inorganic Chemistry. By G. S. Newth, F.I.C., F.C.S. Pp. xiii. 667. (London: Longmans, Green, and Co., 1894.)

THE author states in the preface, that the arrangement of the course of elementary instruction in chemistry, which is given in this book, is based on the periodic classification of the elements. The properties of four elements, *hydrogen*, *oxygen*, *nitrogen*, and *carbon*, and the properties of many compounds of these elements, are considered before the systematic study is entered on, of the groups into which the elements are divided by the application of the periodic law. Then follow chapters wherein the members of the various groups of elements, and the chief compounds of these elements, are described. To this descriptive part of the book are prefixed fifteen chapters of "introductory outlines," constituting "a brief sketch of the fundamental principles and theories upon which the science of modern chemistry is built." In his directions to students using the book, the author says that a start should be made by reading carefully the chapters dealing with chemical change, elements and compounds, nomenclature, and symbols; that the four typical elements—hydrogen, oxygen, nitrogen, and carbon—should then be studied; and that, as this study is proceeding, the remaining chapters of the "introductory outlines" should be mastered.

It seems to me that the method of the author is radically wrong. Descriptive statements of facts ought, surely, neither to precede, nor to follow, but to accompany, the reasoning on these facts whereby general principles are gained.

The author's treatment of chemistry implies that "the science of modern chemistry is built" on the foundation of such generalisations as those stated in his "introductory outlines," and that detailed descriptions of the properties of certain kinds of matter called elements and compounds constitute the science that is raised on this foundation. Would it not be more advisable so to treat the subject as to show that chemistry rests on certain definite natural facts, but that only when these facts are compared, contrasted, and classified, does a scientific knowledge of them begin?

The descriptions in this book of the members of each group of elements seem to me to be exceedingly well done; many portions of the chapters treating of principles and theories, notably the pages which deal with the laws of chemical combination, are admirable; nevertheless the book, as a whole, gives the impression of being unscientific. The method of the book tends, in my opinion, to perpetuate the vicious and unreal distinction between chemistry and chemical philosophy, a distinction that has probably been as potent as any other cause in stopping the progress of the science.

The purely descriptive portions of this work are often extremely good, as far as they go. The facts, or rather half-facts, are stated in a clear and orderly way; care is taken to notice recent work of importance; the woodcuts are well executed: but, all this is only the material out of which chemistry is constructed.

About 130 pages are devoted to statements of the properties of four typical elements—hydrogen, oxygen, nitrogen, and carbon—and of the properties of many compounds of these elements. But hydrogen, oxygen, nitrogen, and carbon are not treated as typical elements they are not compared and contrasted with other elements. After reading the descriptions of these elements and their compounds, and studying the properties of the elements in each of the eight groups of the periodic classification, one still feels unsatisfied. Something is lacking. Surely some fair and fitly fashioned building ought to rise on this broad superstructure. If chemistry is to be treated as a recitation of disconnected, or artificially connected, facts, it ceases to be a subject worthy the serious attention of educated men. One turns to a new book on elementary chemistry, hoping to find at least an attempt to rescue chemistry from the overwhelming burden of so-called facts, beneath which the science is in danger of being buried. In this case I confess to disappointment. It may be replied that the chemistry which is not clearly apparent in the purely descriptive parts of the book is to be found in the "introductory outlines" wherein the "fundamental principles and theories" of the science are stated. I admit at once that there is much excellent matter in these earlier chapters; but I do not find there a connected setting forth of elementary principles, as arising from facts, and binding facts into some kind of harmonious whole. There is not much either exact or imaginative treatment; and these two I take to be the notes of genuine science.

The perusal of this book produces in one's mind a strange feeling of inversion; many things seem to be standing on their heads. The reader feels that a rapid mental rotation, to right or left, is demanded. Change is very properly said to be the feature of all chemical occurrences; but at a very early stage (p. 5), after two pages have been occupied in lightly touching the subject of the constitution of matter, the student is told that "Any change which arises from an alteration in the structure of the molecule is a chemical change." This is an example of the topsy-turviness of parts of the book. The statement quoted has a meaning when the meaning of such a very symbolical expression as "structure of the molecule" has been adequately grasped. At this stage of progress the student cannot have any clear image called up in his mind by the words I have quoted; they must be merely words to him. But he might have grasped the prominent and characteristic features of chemical change had these been put before him by well-chosen experiments. Another instance, to my thinking a glaring instance, of putting theory where facts should come, and facts where theory, is found in chapter ii., which deals with elements and compounds. The distinction between these classes of substances is stated at once, and is stated only, in the language of atoms and molecules.

"In the substance sulphur, all the atoms composing the molecules are alike; while in water . . . there are two distinct kinds of atoms in the molecule. Matter, therefore, is divided into two classes, according as to whether its molecules are composed of similar or of dissimilar atoms. Molecules consisting of atoms of the same kind are termed *elementary molecules*, and substances whose molecules are so constituted are known as elements."

The chapter which deals, and deals in a clear and most praiseworthy style, with the laws of chemical combination, is headed "The Atomic Theory." I think the author must have taken his own words too literally (p. 29):

"Dalton embraced the ancient doctrine of atoms, and extended it into the scientific theory which is to-day known as Dalton's atomic theory, and is accepted as a *fundamental creed* by modern chemists." (The italics are mine.)

A "scientific theory" and a "fundamental creed" are very different things.

For his descriptive treatment of the materials from which chemistry is built up, I think the author is to be praised; but I do not think he has succeeded in setting forth the principles of the science of chemistry clearly, adequately, or in fitting order.

M. M. PATTISON MUIR.

OUR BOOK SHELF.

Astronomia Sferica. An Elementary Treatise. By Francesco Porro. (Roma: Società Editrice Dante Alighieri, 1894.)

IN these 160 pages, the author has endeavoured with success to bring before his readers, in as simple a way as is consistent with the subject, the elements of spherical astronomy. With the exception of a small knowledge of the rudiments of the differential calculus, the mathematical ability is by no means taxed. The order in which the subject-matter has been arranged, and the field which is covered, can be gathered from the following short summary. After dealing first with the sphere generally, and the form and daily motion of the earth, the annual motion round the sun, and the methods of the transformation of coordinates, the measurement of time is next explained, in which Kepler's equation, the equation of time, and the transformation of mean into sidereal time, and *vice versâ*, are discussed. Then follows a chapter in which the movements of the moon are clearly expounded.

Diurnal parallax and refraction, the variations of the fundamental planes, aberration and annual parallax, form the subjects for the next three chapters; while the remaining ones are devoted to the determination of the positions of stars and their proper motion, and to the solar system in general. In the last-named, the apparent movements of the planets, the theories of Copernicus and Kepler, the necessary data for the determination of planets' orbits, &c., are touched upon.

From the above it will be seen that the most necessary points for the student have been dealt with, but they have not been treated at too great a length. As an introduction to higher works, this book will be found most useful; but its use in this country will be to a great extent restricted, owing to it being printed in Italian.

The New Technical Educator. Vol. iv. (London, Paris, and Melbourne: Cassell and Co., 1894.)

THE previous volumes of this work have been duly noted in our pages. Volume iv. is in every way up to their standard of excellence.

The subject of the manufacture of iron and steel occupies the first part of the volume. The author of this seems to be well acquainted with the practical details. We note that he appears to consider that the presence of but 0·05 per cent. of sulphur in steel is more or less harmful, producing a metal sensibly red-short. This may be the case; but it is generally considered that the percentages of phosphorus, sulphur, or silicon must not each exceed 0·06 per cent., and then their effects may be overlooked in axles, tyres, plates, &c. Engine-tyres are said to give a tensile test of 46 tons per square inch, with a minimum elongation of 20 per cent. in a 3-inch length. These results are rather extreme, with a sectional area of ½ square inch of test-piece. If the extension exceeds 16 per cent. the result may be considered good with this tonnage.

As in previous volumes, we find much interesting information on cutting tools, from the pen of Prof. R. H. Smith, dealing principally with lathes, drills, and punching and shearing machinery. Different metal shavings are illustrated from photographs, and clearly show the nature of the different metals. The steel shavings shown, however, are not sufficiently described. Cases are known where shavings from a 2½-inch drill working on cast steel have been obtained many feet in length, the material, of course, being of very excellent quality.

The illustrations of drilling machines are good, but all appear to have the ordinary power feed; in many cases it is found advantageous to have, besides the power feed, a quick hand feed in addition, in conjunction with a power attachment, the quick hand gear being used to withdraw the tool in all cases. These motions are very handy in boiler shops, where the same machine may have to drill rivet-holes out of the solid, rhymer or enlarge punched holes, and finally countersink holes, all requiring different feeds.

The continuation of the steam engine in this volume includes boiler fittings and details, efficiency of the engine and engine and boiler trials, concluding with a chapter on compound engines. The latter parts of these chapters are well written and interesting. The classical work of the late Mr. Willans is largely drawn upon, as well as the trials carried out by the Institution of Mechanical Engineers, besides careful descriptions of other steam-engine trials. The combination of indicator diagrams of compound or triple expansion engines is wel explained.

A series of articles on engineering workshop practice is commenced, and they are very good so far as they go, but it may be suggested that engineers' shop appliances as generally used should be described, and not the "elegant amateur tools," such as are illustrated in Figs. 29 and 77. N. J. L.

Index Kewensis Plantarum Phanerogamarum. Sumptibus Beati Caroli Roberti Darwin ductu et consilio Josephi D. Hooker, confecit B. Daydon Jackson. Fasciculus iii. (Oxoni: E prelo Clarendoniano, 1894.)

THE third fasciculus of the Kew Index, which the Clarendon Press has just issued, brings us within sight of the completion of this monumental work. This part brings the Index down to near the end of the letter P, and we may look forward then to seeing in course of the coming year the concluding fasciculus. Since we noticed the earlier fasciculi there has been no new development in the nomenclature controversy, upon which, we believe, the Kew Index will exercise an important influence; the effect of this will likely be only apparent after the whole is published. Meanwhile the sterling value of the Index is increasingly evident, and every botanist will congratulate the preparers and the publishers upon the appearance of this third fasiculus, in which the same careful and conscientious workmanship is noticeable as characterised the portions of the work previously issued.

Alpine Climates for Consumption. By H. J. Hardwicke, M.D. Pp. 65. (London: J. and A. Churchill, 1894.)

THE high-altitude cure for acquired and hereditary consumption has gained ground in the medical world during recent years, with the result that numerous winter health stations have sprung into existence in Switzerland. Dr. Hardwicke's little brochure has been written for the purpose of providing trustworthy and unbiassed information with regard to some of these resorts. It is pointed out that the principal requirements of an Alpine winter climate in the treatment of phthisis are (1) high altitude, (2) low temperature, (3) dry atmosphere, (4) large amount of sunshine and ozone, (5) low atmospheric pressure, (6) freedom from wind, (7) freedom from organic and inorganic particles in the air, (8) absence of fogs, (9) good water-supply, (10) good drainage. The author believes that stations possessing all these properties are extremely beneficial to consumptive patients. His book will help sufferers from lung disease to the selection of a suitable winter residence.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

"Acquired Characters."

IT may be at once conceded that persons who discuss whether "acquired characters" are inherited or not, ought to know and to be able to state clearly what is meant by the term "acquired characters."

I am surprised that Sir Edward Fry should find any difficulty in ascertaining what should be meant by this term when used in the case to which he refers, viz. the theories of Lamarck and of Darwin with regard to the origin of the species of plants and animals. Sir Edward Fry seems to assume that the matter under discussion is contained in certain writings by Prof. Weismann as though those writings were a sort of "affidavit," binding and limiting the discussion. The fact is that Prof. Weismann is a witness—and an advocate too—in a case which is of more ancient date than his connection with it.

Sir Edward Fry has found some satisfaction, as have many other writers, in pointing out inconsistencies and ambiguities in Prof. Weismann's statements; but it is to me somewhat astonishing that one should be invited to a textual criticism of Weismann's words in order to ascertain the significance of the term "acquired characters." The term and the discussion about the inheritance or non-inheritance of acquired characters were not invented by Weismann! They have been familiar ever since the discussion of Mr. Darwin's book on the "Origin of Species," commenced thirty-five years ago. The term has been explained and amplified over and over again. It really dates back to Lamarck; and I should propose, when anxious to know the meaning of a term associated with Lamarck's doctrine, to investigate Lamarck's writings rather than Weismann's.

Lamarck's "Philosophie Zoologique" was published in 1809. On p. 235 of vol. i. of the reprint of this work, issued in 1873 under the direction of Prof. Charles Martin, Lamarck states his two "laws" of organic development. They run:—

Première Loi.—"Dans tout animal qui n'a point depassé le terme de ses développements, l'emploi plus fréquent et soutenu d'un organe quelconque fortifie peu à peu cet organe, le développe, l'agrandit, et lui donne une puissance proportionné à la durée de cet emploi; tandis que le défaut constant d'usage de tel organe l'affaiblit insensiblement, le détériore, diminue progressivement ses facultés, et finit par le faire disparaître."

Deuxième Loi.—"Tout ce que la nature a fait *acquérir* ou perdre aux individus par l'influence des circonstances où leur race se trouve depuis longtemps exposée, et par conséquent, par l'influence de l'emploi prédominant de tel organe, ou par celle d'un défaut constant d'usage de telle partie: elle le conserve par la génération aux nouveaux individus qui en proviennent, pourvu que les changements *acquis* soient communs aux deux sexes, ou a ceux qui ont produit ces nouveaux individus."

I have italicised two words in this quotation. It is to this doctrine of Lamarck that the short term "doctrine of acquired characters" has been and is applied.

In the report of a lecture given by me, at the London Institution, in February 1889 (published in NATURE of that date), on "Darwin *versus* Lamarck," the two laws of Lamarck were quoted in full. In lectures given some three years earlier I had pointed out that there is no satisfactory evidence that animals or plants transmit by generation the characters acquired by the individual in the way supposed by Lamarck.

It is, I admit, a very difficult matter to determine whether a particular character which makes its appearance in the course of the life of an organism has been "inherited" (*i.e.* is congenital) or "acquired." But that has nothing to do with the question as to what we should mean when we say "acquired characters." The answer to that seems to be certain and simple. It is given by Lamarck, and the term directly refers to Lamarck's doctrine.

On the other hand, it is the fact, as Sir Edward Fry points out, that Weismann and others have employed the term "acquired characters" in an extended and modified sense. To this extension I will refer in another letter.

E. RAY LANKESTER.

WE must all agree with Sir Edward Fry's desire to obtain a clear and exact definition of an "acquired character," as this term has been used in the discussions upon hereditary transmissibility. I do not think, however, that those who have taken part in the various controversies and discussions which have raged intermittently during the last seven years, have been misled by the lack of a sufficiently exact definition or the multiplicity of inexact ones. I believe that both sides have known well enough the kind of character which was called acquired, even though no sufficiently clear definition was forthcoming. And it may be that this mutual understanding has tended to obscure the demand for a definition.

An acquired character has generally been briefly defined as "the result of the operation of some external force upon an organism," and I still think that this is as satisfactory as any definition of equal brevity can be. But some want of clearness follows from the elasticity of the word "result." Everything that follows the operation of some external force may be called its "result"; but the definition interpreted in this way would include much that is not within the meaning of the word "acquired." Some increased precision may be added by using the words "direct result"; but a perfectly satisfactory definition should, I think, imply the admission that the result (in its wide sense) of an external force on an organism must always contain elements which are not due to the force—which are not acquired—as well as those which are due to the force and which are acquired. I think that the following definition will meet the case: "Whenever an organism reacts under an external force, that part of the reaction which is directly due to the force is an acquired character."

In many cases the external force acts only as a shock, with the *starting* of reaction as its only direct result. In such a case the occurrence of the reaction, as contrasted with the sequence of events which make up the reaction itself, is the acquired character. In examples such as these, those who maintain the transmission of acquired characters would be required to prove that the reaction which could only be started by an external force in the parent, started without this stimulus in the offspring.

I believe the definition suggested above meets all Sir Edward Fry's conditions—viz., that it includes all "acquired" characters, and excludes all that are not acquired; that it is physical and not metaphysical; that it is not "stated in terms derived from hereditability or the contrary, or in terms of any hypothesis or theory"; and that it admits of ascertainment and verification.

That a reaction under an external force is compounded of two parts, due respectively to the body which reacts, and to the force which causes the reaction, is a fact and not a theory or hypothesis. It may be urged, however, that the separation of the two constituents does not admit of "ascertainment and verification." This may be true, in the present state of our knowledge, for certain cases; and if so, these cases would be unsuitable for the purposes of an inquiry into the transmissibility of acquired characters. But I do not admit that it is proved that the two constituents of the reaction cannot be separated in every case by a sufficiently careful investigation. For the purposes of this inquiry it is sufficient, however, if we can prove beyond doubt that some part of a reaction is the direct result of an external force, even if we have not thereby exhausted the whole of the direct results contained in the reaction. For if this can be done in a vast number of cases, an immense body of evidence will be provided, and we may expect that, if acquired characters are transmissible, some proof will be forthcoming.

I propose to test the efficiency of the definition given above, by showing how it can be applied to some of the examples given in Sir Edward Fry's letter.

In the case of the "exercierknochen" it is clear that the *occurrence* of the reaction—the existence of the bony growth—is the direct result of the external force. Here then is an acquired character which will be admitted by everyone, which can be witnessed in a vast number of examples, and which can be conveniently applied to test the transmissibility of such characters. There may, or may not, be other direct results contained in the reaction: some of the processes of osseous growth may have followed directly from continuous or intermittent pressure. But in the first place the verification is much more difficult, although not, I believe, beyond the reach of scientific inquiry, and, in the second place, such proof, if obtained, would yield evidence which would be far more difficult to obtain in very large quantity.

It is clear that when Prof. Weismann admits that "the periodical change of leaf in temperate climates has been produced *in relation to* the recurring alternation of summer and winter," he is referring to the selection of inherent characters, and not the production of acquired characters. The sentences which follow the one quoted (p. 406), leave no doubt upon this point. Sir Edward Fry may feel assured that when any direct results of heat, cold, air, food, moisture, gravity, or light upon the organism are proved to be heritable, the controversy is at an end.

The case of geotropism logically resembles that of the "exercierknochen." The *occurrence* of the reaction is certainly a direct result of the external force—an acquired character; and here too we have an immense body of evidence to which to appeal, and which points only in one direction. In spite of the innumerable generations during which plants have assumed certain relative proportions under the influence of gravity, this influence is just as necessary to-day as it has ever been, and the youngest generation starts unbiassed by the direct result of external forces upon its ancestors.

As regards the "extra fingers or toes, patches of grey hair, moles, &c.," the question is raised as to whether external forces are not involved as direct causes. If this can be proved the question at issue is settled, for such characters are known to be transmissible. If not, the observation merely shows us that certain characters, not proved to be acquired, are transmissible. But if the non-transmissibility of those proved to be acquired has been established on a sufficiently large scale, then the observation in question, accompanied by the continued absence of proof that the characters in question are acquired, may be fairly held to indicate the existence of two contrasted classes of characters, which we may call spontaneous or inherent, and acquired.

We are asked if we have any scientific knowledge of the organic world independently of any external influence. This method of eliciting an answer must not be allowed to disguise, as it appears to do, the very positive knowledge we possess of the separate effects of the several external influences. This is a legitimate province of scientific investigation, and a large amount of research at the present day is devoted to such questions.

In handwriting the two constituents of the reaction are somewhat difficult, but by no means impossible, to distinguish. The external influence of training operates upon the most complex part of the organism, the nervous system, which again directs the muscular system. Is the style of handwriting due to the external force, or the organism which reacts? We can eliminate pen, ink, and paper as influences by only considering the cases in which these have been identical. There remains the influence of the teacher, and in order to prove that this has been the direct cause of style, it must be shown that the teacher had produced the same style in many pupils. If a style so produced became hereditary, evidence of transmissibility of an acquired character would be provided. Conversely, variety of style under the same conditions of teaching, &c., would favour the view that we are not dealing with an acquired character in this part of the reaction.

It is unnecessary to consider further the cases of mutilation and wounds, for I imagine that Prof. Weismann, and all who agree with him on this subject, will be willing to accept the clear statements of Sir Edward Fry's letter. "What the organism transmits is the capacity or predisposition, and not the actual result of the reaction." The latter in these cases is an acquired character, while no one has ever shown that there is any probability that the former is acquired.

I have, in this letter, avoided reference to many points raised by Sir Edward Fry, not from want of interest or inclination, but in order to keep to the main issue—the attempt to furnish a clear definition of the class of characters in question.

If acquired characters are transmissible, we must expect that sooner or later among the vast body of characters which are or will be admitted on all hands to be acquired, some valid instances of hereditary transmission will be forthcoming.

Such cases as that mentioned by Dr. Hill in NATURE of October 25, when on a sufficient scale and adequately sifted, would supply the requisite evidence. But up to the present such satisfactory evidence has not been forthcoming, although it has been sought for by many observers. EDWARD B. POULTON.

Oxford, November 4.

THE following seems a passable definition, such as Sir Edward Fry asks for in his letter of November 1. But, in offering it, I only speak of the sense in which I myself use the expression.

Characters are said to be acquired, when they are regularly found in those individuals only, who have been subjected to certain special and abnormal conditions.

FRANCIS GALTON.

Science Teaching in Schools.

TWO articles have recently appeared in NATURE which call for some comment, if the columns of your journal are to be opened once more to a discussion of this question. Educational reformers will agree heartily with the general position taken up by Mr. H. G Wells, in "Science, in School and after School" (vol. l. p. 525), and by Prof. Armstrong in "Scientific Method in Board Schools" (p. 631). But they either ignore or give very little credit for the honest science teaching that is actually being done at the present time. I realise, only too personally, the great difference between training in scientific method and mere instruction in science; and how few are the attempts to make use of the former in all grades of schools. But I hold that the old-fashioned instruction in science has, under favourable conditions, a considerable *educational* value. To have enabled a boy to realise the composition of the air and water is to have introduced him to the world of nature, and has widened his ideas and conceptions to an extent which justifies the means. Was not this one of the original pleas for the introduction of science into the school course? But having entered my protest, I will pass on.

Mr. Wells admirably distinguishes between the two styles of science teaching, and points out the original function of the Science and Art Department in encouraging and examining only the one of them. But he admits that the field of operation of the Department has been very much widened in recent years, and that its examinations "seriously affect the teaching of middle-class, and even of the higher standards of elementary schools." Yet his only suggestion is that the Department should withdraw from this work; for that would be the effect of an age limit, and is intended to be the effect of the recent alteration in the regulations in the elementary stage.

But circumstances are such that the Department cannot and ought not to withdraw from its present control of science teaching in *day-schools*, for its influence is greater than that of any other examining body; not simply financially, but from the magnitude of its operations. It is a historical quibble to say that the Department is concerned primarily with continuation and adult classes, when it specially encourages the formation of organised science day-schools, and yet rigidly confines the teaching in them to the schedules devised for adult instruction.

Last session there were 94 organised science day-schools, containing about 10,000 pupils taught on the lines laid down by the Department. As is well known, the majority of these are what are otherwise known as Higher Grade Board Schools, which are absolutely dependent for their existence on the grants obtained from the Department. I take it as indisputable that this is the very class of schools where the science ought to have an educational basis; where its function is "to develop and train the hand, eye and mind together, enlarge the scope of the observation, and stimulate the development of the reasoning power." I also believe that many of the teachers are anxious to make it so, judging from their liberal denunciations of the present "pernicious system." Equally axiomatic is it that, under the Science and Art Department, it is impossible to indulge in such teaching. Time will not permit. The pressure is so great that oxygen and water are almost always written and spoken of as O and H_2O.

Mr. Wells considers other examining bodies, whose work is exclusively directed to school needs, are far more blameworthy. This I absolutely deny. In the first place, the South Kensington examinations are the only ones which are entirely controlled by scientific men. The sole cause for the existence of the Department is the encouragement of science and art, whereas the other bodies referred to provide for the examination of secondary education generally; and the examining board may not have a single representative of science upon it. But further, assuming that the South Kensington examinations are neither better nor worse than others, there are two causes which make them an educational abomination.

(1) In one year the pupils have to be rushed through such an excessive amount of work that the teaching degenerates into the merest cram. The Department distinctly states that students in the first year are to be prepared for the first stage, and in the second year for the second stage. Putting aside entirely the consideration as to whether the scheme is any particular subject, as chemistry, will any practical teacher deny that the requirements for either the first or second stage are far beyond what it is possible to accomplish with satisfaction within the given time? It must be kept in mind that the time-table has to provide not only for the seven or eight subjects of which the Department takes cognisance, but "for instruction in those literary subjects which are essential for a good general education." Do not these latter often suffer in favour of the former, especially at the approach of May?

(2) The consequence of this restriction is that boys scarcely in their teens enter by thousands for an examination beyond their normal capacities. It is in this that the South Kensington examinations differ so entirely from those of the Universities. The difference in standard between the Department's examination in chemistry and the Cambridge Junior Locals or London Matriculation is not great; but in practice, the average age of candidates in the latter is higher by two or three years. Time is allowed for the awakening and development of the powers of observation and reasoning. A boy is then able to describe intelligently what he has become thoroughly familiar with, instead of reproducing mechanically his notes or text-book.

In still another particular have the University Boards a decided advantage. Either they dispense altogether with an examination in practical chemistry, or they make something more of it than an analytical drill. Not much, it is true, but it must be remembered that practical chemistry is the most perverted subject in the whole range of knowledge at the hands of both teachers and examiners. But the greatest mockery is that which passes under the name at South Kensington. Of the written part of the examination it is needless to say anything; no boy would regard it as a test of what he has done in the laboratory, but what he has seen in the lecture-room. As to the analysis of salts, what bearing has it on the chemistry he is being taught elsewhere? Though at a certain stage it has a considerable educational value, the amount of time wasted upon it is appalling. It is useless to reiterate how easily it lends itself to being converted into a mechanical grind.

Mr. Wells is of the opinion that the recent abolition of the second class pass in the May examinations has had a beneficial effect. So it may, in extinguishing what might be termed "bogus" classes. But it has only intensified the evils in organised science schools, and put a higher premium on the cleverest cramming. The change did not deter such schools from sending in their pupils as before, but now they had to obtain 60 per cent. of the possible marks, or fail—and most of them failed. This year there were fewer failures, because the teaching has answered to the whip. Financially the result is satisfactory to them, but educationally it is disastrous. At that age the average boy is not capable of obtaining more than forty or forty-five per cent. of the marks in such a subject as chemistry. Very often he does not understand the full meaning of the question; and when he does, he is unable to write down more than a moiety of what he knows, or what could be drawn from him by a series of oral questions. There is no consideration shown for the immaturity of the candidates, but the standard is pitched higher than that of any other public examination in the country.

So far from agreeing with Prof. Armstrong that science must be admitted to equal rights with the *three R's*, I hold that it is taught too extensively as long as the present system of examination prevails, and that the first battle to be fought ought to be against the South Kensington examinations, until they truly perform their double function. W. B. CRUMP.

Heath Grammar School, Halifax.

WILL you allow me to take the opportunity afforded by the publication, in NATURE, vol. l. p. 631, of Prof. Armstrong's address at the Berners Street Board School, to offer my testimony to the value of teaching, based on the principles which he advocates so eloquently? The *practical* difficulty of teaching what Prof. Armstrong has called scientific method in an ordinary school, is often the ground of the objection made to it, so that it may interest your readers to hear of any experiments in this direction.

My work has been amongst girls, and the attempts made thus far in teaching scientific method in girls' schools show that such a method will inevitably lead to the development desired by Prof. Armstrong.

Doubtless one of the drawbacks is the difficulty of giving to each member of a large class the opportunity of individual work. I am not sorry, however, to have sometimes laboured under this difficulty myself, as it has brought about the discovery of how much could still be done on the right lines. When necessary I have replaced individual work by a demonstration class, in which the pupils, three or four at a time, have taken it in turns to work in front of the others, the work consisting in the solution of problems such as those suggested in the British Association's report on chemical teaching. The principal results are these: the children take a growing interest in the work, and those who are doubtful how far girls may desire to work with their hands, instead of always sitting still, may be glad to hear that no greater incentive to invention can be given in a demonstration class than the reward of becoming the experimenter for the time being. There is never any lack of suggestion for the next step in the work, and the rapidity with which such work trains the girls to consider the value or defects of any new proposal for the solution of their problem, is sometimes astonishing. In these classes the teacher plays a very small part—at least, apparently—only from time to time directing the suggestions, and giving permission for new work to be started; invention, experiment, meaning of results, and criticism are all undertaken by the children, and the final "discovery" is their own triumph.

I have often been asked by teachers about the discipline of such a class, since experimental work goes so slowly that they think it would be impossible to keep those who are not actually at work attentive. I can only say that the class consists of a group of people genuinely interested in a common object, and it behaves in the way such groups generally do. If at times a girl's enthusiasm so far carries her away that she rushes from her seat to the experimenting table, the class, with a laugh, excuses her, sympathises with her feelings, and is not disturbed thereby.

It seems unquestionable that the result of such work should have a wider-reaching effect than the mere knowledge of certain facts in nature, though such knowledge is also obtained. Where children, through their own work, have been led to observe and then to think, the result may fairly claim to be truly educative, and one is often at a loss to understand what support can be found for the still largely-existing method of teaching not science but "useful information."

Another objection often made to teaching scientific method instead of facts, that it takes too much time, I have already answered in this journal. I may perhaps be permitted to repeat that experiment shows the result of elementary training, of the kind described, to have a lasting influence on the rapidity and comprehension with which new subjects are grasped later on. Books, too, which are never put into the hands of beginners, are used with more than ordinary sense at this later stage. I may say that, even from the examination test (which, however, is not always going to be our standard), the results are very favourable. One thing, however, cannot be done by the teaching of scientific method, and that is to prepare for the London Matriculation examination in chemistry in three months—but then, is that altogether to be regretted?

GRACE HEATH.

North London Collegiate School for Girls, November 5.

Italian Scientific Expedition to Monte Rosa.

IN the summer of this year, my assistant Dr. L. Scofone and I stayed a month at the Alp of Lavez in the valley of Gressoney, near the foot of the Indren glacier, at an altitude of 2450 m., not far from the place where the brothers Schlagintweit spent some days in 1851 while engaged in their well-known scientific observations on Monte Rosa.

We purposed to examine, both chemically and bacteriologically, the composition of the waters of that region (inclusive of snow and ice); some of the analyses (ammonia, nitrites, nitrates and organic matter) were made directly on the spot, where we had a small laboratory. To be able to carry the waters to Turin, for further analysis, we had only to evaporate them, and seal the residues in little glass bottles by means of a blowpipe. The detection of germs was made by using agar and gelatine plates enclosed in the well-known Petri's glass-boxes; gelatine, agar, pipettes, and other instruments being duly sterilised first in Turin, and then at Lavez, with a good hot air oven. The development of germs was secured by putting the plates in an incubating oven.

We also collected the water of the Indren torrents issuing from the glacier, and measured the amount of suspended matter in the water, which can give an idea of the process of erosion that takes place in the bed of the ice stream.

The results of the various observations will be published in the scientific papers of Turin as soon as the study of the collected material has been completed. It will perhaps interest your readers to know that while the water of the springs, streams and lakes was constantly free from ammonia, there was found a tolerable quantity of it in the snow collected on the summit of the Punta Guifetti or Signal Kuppe, one of the loftiest peaks in the Monte Rosa range, measuring 4539 m. The ice of the Lys Glacier, dug out from the depths of a huge crevasse, also contained ammonia; nitrites and nitrates being absent in every case. Accordingly we found that the water of the Indren stream, during a very hot day, when the melting of the ice was considerable, contained traces of ammonia.

We also found that the ice and snow collected on the various peaks, passes, and snow-fields of the Monte Rosa range, contained a few germs. The number of the species whose germs can thrive at those heights is certainly not large; the usual forms, living in decayed matter and in the intestines, cannot probably endure the condition of temperature, pressure and light of the place.

Turin, October 28. PIERO GIACOSA.

Chinese Beliefs about Caves.

MR. HERBERT SPENCER, in his "Principles of Sociology" (3rd edition, New York, vol. i. p. 207), relates the beliefs in the creation of mankind under the ground or in caverns, current among the Todas in Asia, the Basutos in Africa, and at least one-half of the American tribes. A similar belief I have lately found in a Chinese record. In Li Shih's *Süh Póh-wuh-chì* (written in the 13th cent. A.D., Japanese edition, 1683, tom. ii. p. 3) a quotation from the *Ning-kwóh-lun* runs as follows:—"Primitively there was no Liáu-Kién in Shuh (now Sze Chuen); this tribe emanated from red clay in a cave of Teh-yáng mountain, whence bits of the soil had began to roll out, each roll enlarging them, so that at last thereby was created a couple, who gave birth to many."

In another paragraph Mr. Spencer remarks:—"Stationary descendants of troglodytes think that they return into a subterranean other-world whence they emerged (*ibid.* p. 213). According to this, I would suggest that the same belief, entertained by some aborigines in China, has revived itself among the Taôists, who used to call their paradise the "Cave-Heaven" (Tung-Tièn)—*e.g.* Twan Ching-Shih describes the "Cave-Heaven" 10,000 *lis* in circumference and 2600 *lis* in height (his "Miscellanies," Japanese edition, 1697, tom. ii. p. 1), and Li Shih enumerates thirty-six caves in the empire, all entitled "Heavens" (*ibid.* tom. i, p. 8).

Spots over Dogs' Eyes.

I WOULD have written a note on this subject long ago, had I not failed to see similar spots general amongst wild animals allied to the dog. The spots may, however, be more general than I am aware. The spots are by no means always tan; a black dog will sometimes have them white, and a white dog black. I have a white-and-tan fox-terrier, in which the spots are very eye-like and jet black; in a brown bull-pug of mine, the spots are also black. These spots are so eye-like, that when the dogs are asleep they seem at first sight to be wide awake.

Has not the human eyebrow, highly developed in some crude races, as in Australians and Ainos, a similar meaning? The eyebrow gives many sleeping persons the appearance of being awake. WORTHINGTON G. SMITH.

Dunstable.

Gravitation.

IN his interesting paper upon the "Mechanical Stretching of Liquids" (*Phil. Trans.* 1892, A, p. 370), Prof. Worthington describes a phenomenon of attraction between bodies immersed in a stretched liquid. His explanation is ingenious: that the close contact of the bodies liberates from a denser surface layer, liquid which will go to supply the prevailing demand, and so lower the energy of the stretched liquid.

Whether this be a quite correct explanation or not, does not the experiment suggest the possibility of an analogous phenomenon occurring in a tensile ether in which matter is immersed; giving rise to the effects which we appreciate as gravitational attraction? J. JOLY.

Trinity College, Dublin, November 6.

Homogeneity of Structure the Source of Crystal Symmetry.

To the lucid notice of my paper, "Ueber die geometrischen Eigenschaften homogener starrer Strukturen und ihre Anwendung auf Krystalle," contained in your issue of October 18, it is perhaps desirable to add a remark.

The paper referred to is purely geometrical; it starts with a definition, and not with a supposition. Consequently the various new theories advanced by the writers referred to in the notice receive no support from it.

Homogeneity of structure pure and simple, unaided by any theory as to the nature of matter, leads inevitably to all the varieties of symmetry presented by crystals. It is useless, therefore, to look to the facts as to this symmetry for any light upon the vexed question whether the seat of the symmetry is in the arrangement or in the configuration of the molecules, or, indeed, for any proof of the existence of molecules or separable units. WM. BARLOW.

Muswell Hill.

THE PRESENT STATE OF PHYSIOLOGICAL RESEARCH.

THE following extracts from an article by Prof. Max Verworn, of Jena, on "Modern Physiology," published in the *Monist* for April 1894, seem to be well worth the attention of English biologists. It would be interesting to obtain in the pages of NATURE an expression of opinion from our physiologists as to how far the reproach is true, that "in treading the beaten paths we are making no progress in physiology, and have stood still for years on the same spot." How far is it true that physiologists must revert to the point of view of comparative physiology, or the physiology of the endless variety of lower and simpler forms of life which was that which formerly so fruitfully shaped the research of the great master Johannes Müller? Is it, or is it not, time that the methods of horological physiology were less dominant and gave place to a determined and persistent study of living structure in many of its varied manifestations other than the frog and the rabbit?

"Psychologically, it is a highly interesting phenomenon, and one of moment in the history of science, that now, almost immediately after the final suppression of the old vitalism by the new development of the natural sciences, we have again arrived at a point which corresponds in the minutest details to the reversion to mystical vitalism which took place after the clear and successful research of the preceding century. As a fact, the parallel between the conditions of the eighteenth century and those of to-day is unmistakable. Now, as then, the physico-chemical method of explaining phenomena of life looks back on a brilliant, almost dazzling sequence of successes; now, as then, the tracing of vital processes to physical and chemical laws has reached a point at which, for many years, with the methods now at our command, no essential progress has been made, where, on the paths hitherto trodden, a boundary line is everywhere distinctly marked; and now, as then, on the horizon of science the ghost of a vital force looms up. It has already taken possession of the minds of serious thinkers in Germany, with the dire prospect of more extensive conquests; and in France, too, it would seem, science is slowly opening its door to this invasion of genuine mysticism.

"To understand this phenomenon psychologically, and to acquaint ourselves with the means of staving off a general reaction into vitalism, it is desirable to examine more carefully the present state of physiology. A review of the productions which appear in our different physiological journals, which will best exhibit the present state and tendency of the science, furnishes an extremely remarkable spectacle. Leaving aside the science of physiological chemistry, which is independently developing with great success, we find, with the exception of a few good contributions to the physiology of the central nervous system, as a rule, only extremely special performances of very limited scope and import, wholly without significance for the greater problems of physiology, whether practical or theoretical, and exhibiting no connection whatever with any well-defined general problem of physiology. In fact, what is called physiology is beginning here and there to degenerate into mere technical child's play. With every new number of our physiological magazines, the unprejudiced observer is gradually gaining the conviction that general problems of physiology no longer exist, but that inquirers, driven to desperation in the struggle for material, have no choice but to hunt up the old dry bones of science, on which they fall with the nervous rapacity of hungry dogs. And in the case of most of the productions, this impression is strengthened by the fact that the results, when once found, are wholly disproportionate to the tremendous expenditure of labour and time which it might be seen beforehand they would require. And yet all the time the great problems of physiology everywhere stare us in the face and seek solution. For, if we regard the problem of physiology as the investigation of the phenomena of life, we are certainly yet very far from the solution of even its most important and most general problems. We need not go to the extreme that Bunge does in his excellent text-book of physiological chemistry, of maintaining that the phenomena of our organism which we have explained mechanically are not genuine vital processes at all, no more than is 'the motion of the leaves and branches of a tree shaken by a storm, or the motion of the pollen which the wind wafts from the male to the female poplar.' But it is certainly no exaggeration to say that what the splendidly-conceived methods of the great masters of physiology since Johannes Müller have explained, are not elementary processes of life, but almost exclusively the crude physical and chemical actions of the human body.

"For what have we attained? We have measured and registered the motions of respiration, the mechanics of the gaseous exchange in the lungs in their minutest details. We know the motions of the heart, the circulation of the blood in the vascular system, nay, even the slightest variations of the pressure of the blood, as produced by the most diverse causes, as accurately as we do the phenomena of hydrodynamics in physics. We know that respiration and the motion of the heart are conditioned by the automatic activity of nervous centres in the brain. But no spirometer, no kymograph, no measuring or registering apparatus can give us the slightest idea of what takes place in the nerve-cells of the brain that condition the beating of the heart and respiration.

"Further, we have investigated the motions of the muscles, their dependence on the most diverse factors, their mechanical powers, their production of heat and electricity, as exhaustively as only the phenomena of the special departments of mechanical physics have hitherto been treated. But of what goes forward in the minute muscle-cells during simple muscular contraction, no myograph, no galvanometer has as yet given us the slightest hint.

"We know also the laws of the excitability of the nervous fibres, of the propagation of irritations, of the direction and velocity of nervous transmission, thanks to the ingenious methods of recent physiology, in all their details. But of what is enacted during these processes in the nerve-fibres and in the ganglion-cell from which it ramifies, no induction-apparatus or multiplicator can give us the least information.

"We know besides, that the heat and electricity produced by the body, and the mechanical energy of muscular work, are the consequence of the transformation of the chemical energy which we have taken into our bodies with our food. But by means of what chemical processes the cells of the individual structures take part in these achievements, the most sensitive thermometer or calorimeter will not disclose, and no thermal pile or graphical apparatus will indicate.

"We might give any number of examples of this kind, but those adduced exhibit distinctly enough the point to be signalised. What we have hitherto attained is this: we have measured, weighed, described, and registered the gross mechanical actions of the human body, for the most part with a degree of precision that would excite the astonishment of the uninitiated; we have also acquired a considerable knowledge of the rough mechanical interactions of the individual organs of the body, the mode of operation, so to speak, of the machinery of organisms. But all that has been done, has been done only up to a certain point; and this point, at which we are brought to a halt, is the *cell*. We have traced all phenomena of change in matter, form, and force back to the point where they disappear in the cell. But of what takes place in the muscle-cell, the ganglion-cell, the lymph-cell, the gland-cell, the egg-cell, the sense-cell, and so forth, we have not the slightest conception. Moreover, we discover here, that even the minutest cell exhibits all the elementary phenomena of life; that it breathes and takes nourishment; that it grows and propagates itself; that it moves and reacts against stimuli. The *elementary* riddles of life, accordingly, have so far defied all research.

"A balance thus cast of the results of past physiological research does not, it must be admitted, exhibit a very encouraging outlook.

"But the resignation of physiology has been strengthened by another prominent factor. This is the attitude of physiological research to psychical phenomena. This attitude is at the present moment a varying one. On the one hand, we still find secretly cherished the vain hope of a chemical and physical explanation of psychical processes, that is to say, of a reduction of them to the motions of atoms, even though Du Bois-Reymond, in his famous address on 'The Limits of Our Knowledge of Nature,'[1] characterised such an understanding as utterly futile; while on the other hand we meet with an absolute resignation in the face of this question—an attitude which is simply a frank acceptation of the conclusion of Du Bois-Reymond's address. Owing to the authority of its author, the 'Ignorabimus' of Du Bois-Reymond has influenced great numbers of inquirers, and produced in physiology a real paralysis of research, so that the abandonment thus effected of the solution of the old problem of explaining psychical phenomena mechanically has caused physiology for the most part anxiously and reverently to avoid any intrusion whatever of psychological questions. On the one side, then, is the idle hope of solving a problem which, despite its being as old as human thought itself, research has not yet even touched; and on the other, an absolute renunciation of any treatment of the problem whatsoever.

CELLULAR PHYSIOLOGY.

"If on the one hand we can justly cherish the hope that the increasing extension of the monistic world-view in natural science will ward off the dangers of a reaction to the old vitalism, the fact nevertheless remains that in treading the beaten paths we are making no progress whatever in physiology, and that we have stood still for years on the same spot, and not approached a single step nearer our goal of explaining the elementary phenomena of life.

"We have reached a turning-point in physiological research which could scarcely be made more prominent. The reappearance of vital force is a token of it. As before all great crises of history portentous spirits appear to clairvoyant people, so in our days the ghost of the old vital force has loomed up in the minds of some of our natural inquirers.

"But striking and obvious as the fact is that we can no longer approach by the old paths of research an explanation of the elementary phenomena of life, still, it is exactly as obvious and striking in what direction there is the only chance or hope of our approaching our goal.

"We have traced the vital processes of man in physiology back to the point where they are lost in the cell. Now, what is more reasonable than that we should seek them out in the cell? In the muscle-cell is hidden the riddle of muscle-movement, in the lymph-cell is hidden the causes of secretion, in the epithelial cell is buried the problem of resorption, and so on. The theory of the cell has long since disclosed that the cell is the elementary foundation-stone of the living body, the 'elementary organism' itself, that in which the processes of life have their seat; anatomy and evolution, zoology and botany, have long since realised the significance of this fact, and the wonderful development of these sciences has furnished a brilliant proof of the fruitfulness of this branch of inquiry. Only in physiology was the simple, obvious, and logical consequence overlooked, and until very recently not practically applied, that if physiology regards it at all as her task to inquire into the phenomena of life, she must seek these phenomena at the spot where they have their origin, at the focus of life-processes, in the *cell*. If physiology, therefore, is not simply content with confirming the knowledge which is already gained of the crude mechanical actions of the human body, but makes it its object to explain clearly elementary and general phenomena of life, it can accomplish this object only as cellular physiology.

"It may appear paradoxical, that although nearly half a century has elapsed since Rudolf Virchow first enunciated in several classical works the cellular principle as a basis of all organic inquiry, a basis on which to-day, indeed, all our ideas in pathology are constructed, physiology still is only just beginning to develop out of a physiology of organs into a physiology of cells. Yet this is the true and normal course of development of science which always advances from the crude to the delicate. And it would therefore be impardonable ingratitude, and a mistaking of the mode of development of human knowledge, if we should seek in the least to underrate the high importance of the physiological research of the past epoch, on whose shoulders in fact we stand, and with whose results we more or less consciously continue our work. Further, in our judgment of the course of development of physiological research, a factor must not be overlooked which controls the development of every science, namely the psychological factor of fashion. The development of every science depends on the stupendous influence of great discoveries. Wherever we cast our eye in the history of inquiry, we find that great discoveries such as, to take the case of physiology, are represented in the works of Ludwig, Claude Bernard, Du Bois-Reymond, and Liebig, deflect interest from other fields and induce a great multitude of inquirers to pursue research in the same direction, with the same methods, especially when these methods have proved themselves so wonderfully fruitful as in the cases adduced. Thus, certain departments of inquiry become, in connection with epoch-making performances, fashionable, and the interest of thinkers in others subsides. But an equalisation in the course of time is always re-effected, for every field of inquiry, every method of inquiry is finite and exhausts itself in time. We have now reached just such a point in physiology: the physiology of organs is in its period of exhaustion. Also the method of cellular physiology will exhaust itself in the course of time, and its place will be taken by other methods which the present state of the problem do not yet require.

But for the present the future belongs to cellular physiology. There are, it is true, inquirers who, although they are convinced of the present necessity of a cellulur physiology, and see perfectly well that the cell as the focus of the processes of life must now constitute the real object of research, yet doubt for technical reasons whether it is possible to get at the riddles of life as they exist in the cell. It may, therefore, be justly demanded that some way, some methods be shown with which a cellular physiology can be founded. The doubt of the feasibility of this undertaking is in great part the outcome of a phenomenon, which, unfortunately we must say, has characterised physiology ever since the death of Johannes Müller, namely, the total lack of a comparative physiology. Physiology has not yet entered on this rich inheritance of the great master. How many among the physiologists of the day are acquainted with other objects of experiment than the dog, the rabbit, the guinea-pig, the frog, and a few other higher animals! To how many are the numerous and beautiful objects of experiment known which the wonderful luxuriance of the lower animal world offers! And yet, just among these objects are to be found the forms which are best adapted to a cellular-physiological solution of physiological problems.

"Naturally, if we believe we are limited, in our cellular-physiological treatment of the riddles of motion, digestion, and resorption, solely to man and the higher animals, we shall encounter in our investigation of the living muscle-cell, lymph-cell, epithelial cell, and so forth, more or less insuperable technical difficulties. And yet the splendid researches of Heidenhain on secretion, digestion, lymph-formation, and so forth, have shown what good results the cellular-physiological method can achieve even here. Well-planned histological experiments, such as those which put the living cell in its intact connection with the remaining woof of the body under given conditions, and then investigate the results

[1] *Ueber die Grenzen des Naturerkennens. Reden. Erste Folge.* Leipsic, 1886.

in the suddenly slaughtered animal, to get from such experiments light on the processes peculiar to the condition of life, undoubtedly furnish the germ of much valuable knowledge. But it is of the very nature of these experiments that they must always remain difficult and restricted, for the *living* object, the tissue-cell, is accessible to microscopic investigation only with the greatest difficulty. Comparatively small difficulties in this respect are offered only by the free-living cells of the organism, as, for example, by the leucocytes or blood-corpuscles. And as a fact, by the researches of Metschnikoff, Massart, Buchner, Gabritchevsky, and many others, we have recently acquired some important and wide-reaching experimental knowledge concerning the vital phenomena of these very objects.

"But if we place ourselves at the point of view of comparative physiology which Johannes Müller represented throughout his whole life with such success and energy, an infinitely broad perspective opens itself up for cellular investigations. A comparative view shows one fact of fundamental importance, namely, that elementary life-phenomena are inherent in every cell, whether it be a cell from the tissues of higher animals or from the tissues of lower animals, whether it be a cell of a plant, or, lastly, a free cell, an independent unicellular organism. Every one of these cells shows the general phenomena of life, as they lie at the basis of all life, in their individual form. With this knowledge, all that it is necessary for the inquirer to do is to select for every special object of experiment the fittest objects from the wealth of forms presented, and with a little knowledge of the animal and plant world, such forms really obtrude themselves on the attention of the experimenter. Accordingly, it is no longer necessary to cleave so timorously to the tissue-cells of the higher vertebrate animals, which, while alive and in normal environment, we can only use for microscopic experiments in the rarest and most exceptional cases; which further, the moment they are isolated from their tissues, are no longer in normal conditions, and quickly die or give reactions that may easily lead to wrong conclusions and to errors. Much more favourable are the tissue-cells of many invertebrate, cold-blooded animals or plants which can be more easily investigated in approximately normal conditions of life; yet even these, as a rule, will not outlast protracted experiments. But here appear as the fittest imaginable objects, for cellular-physiological purposes, free-living unicellular organisms—namely, protists. They seem to be created by nature expressly for the physiologist, for they possess, besides great powers of resistance, the incalculable advantage of existing in a limitless variety of form, and of exhibiting, as the lowest organisms that exist, all phenomena of life in their simplest conditions, such as are not to be found among cells which are united to form tissues, on account of their one-sided adaptation to the common life of the cellular colony.

"Concerning the application of experimental physiological methods to the cell, we need be in no perplexity as to which we shall choose. In the luxuriant multiplicity of form which this world presents, there can always be found for every purpose a great number of suitable objects to which the most different special methods can be capitally applied.

"We can, to begin with the simplest method, apply in the easiest manner imaginable to the free-living cell the method of simple microscopic observation of vital processes. In this manner mere observation has furnished us knowledge of the individual life-phenomena of cells in many details, and also of their mutual connection. Among the most recent achievements of this simple method may be mentioned only the extremely valuable knowledge concerning the more delicate and extremely minute circumstances of fecundation and propagation which Flemming, Van Beneden, the Hertwigs, Strasburger, Boveri, and many others have gained in recent years, partly from living cells and partly from cells fixed in definite conditions of life.

"Moreover, we can also conduct under the microscope vivisectional operations on unicellular organisms in exactly the same scope and with greater methodical precision than can be done on the higher animals. Several inquirers, as Gruber, Balbiani, and Hofer, have already trodden this path with great success, and a considerable group of researches has shown distinctly enough the fruitfulness which this cellular vivisectional method of operation promises for the treatment of general physiological problems. With this vivisectional method also Roux, the Hertwigs, and others conducted their splendid investigations on the 'mechanics of animal evolution,' by showing what functions in the development of animals fall to the lot of the different parts of the egg-cell, or to the first filial cells that proceed from their division.

"We can also apply here, in its whole extent, that powerful physiological method known as the method of irritation, and investigate the effects of different kinds of irritation on the life-phenomena of the cell or of different cell-forms. The vegetable physiologists have already collected a great mass of material in this field. But also in the department of animal physiology a great number of recent works have endeavoured to prove that the phenomenon of irritation which takes place on the application of chemical, mechanical, thermal, galvanic, and luminous stimuli to unicellular organisms are of the greatest importance for the phenomena of life generally.

"Finally, we can approach the life-phenomena of the cell chemically, although in this direction only the very first beginnings have been made, seeing that the microchemical methods have been hitherto little developed. Nevertheless, the labours of Miescher, Kossel, Altmann, Zacharias, Löwitt, and others have already shown that the microchemical investigation of the cell has a future of great promise."

INK-CRYSTALS.

THE pictorial representations of the forms taken by ice-crystals are familiar to everyone; and many young observers have been grievously disappointed with the difference between nature's handiwork and artistic fancy, as exemplified by the ice-crystals really seen and those which embellish scientific works. These "ice-

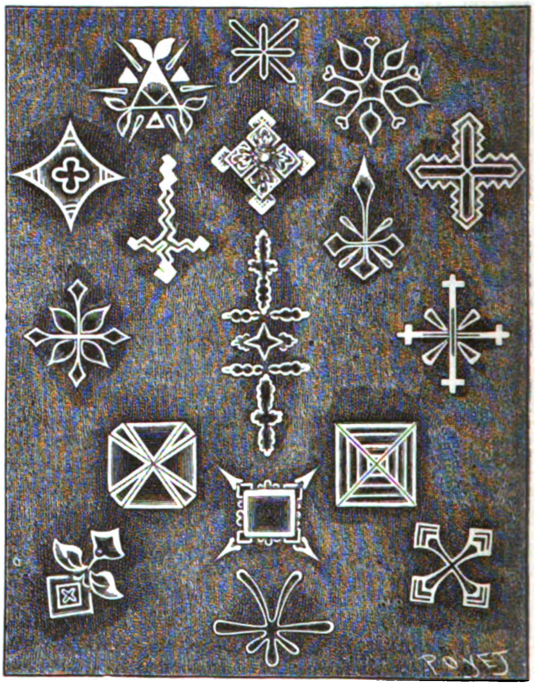

FIG. 1.—Crystals formed by the Evaporation of Ink.

flowers," as Tyndall called them, cannot always be conveniently produced, so a substitute for them, in the form of "ink-flowers," should be interesting to students of crystallography. Dr. E. Trouessart describes in *La Nature* how "fleurs de l'encre" can be procured, and the accompanying illustration reproduces some of the forms observed by him. The method employed is very simple. A drop of ink is allowed to dry on a slip of glass, and observed under a microscope with powers of

50, 100, or 200 diameters. The inks of commerce vary somewhat in composition, hence the facility with which certain crystalline forms are obtained differs. All inks, however, having a base of solution of gall-nuts and sulphate of iron, give analogous results.

Dr. Trouessart hesitates to express an opinion as to the nature of the salt which crystallises in the forms illustrated. The crystals chiefly belong to the cubical system, and this suggests that they are magnetic oxide of iron. On the other hand, their white colour, and the peculiar shapes of some of the groups of crystals, indicate that iron disulphide or marcasite is the substance in question. Perhaps some worker in chemical crystallography will determine the point.

NOTES.

WE learn from the *Lancet* that the late Prof. Pouchet, of the Muséum d'Histoire Naturelle, has bequeathed his entire fortune to the Paris Society of Biology. The bequest is made in the following terms: "N'ayant pas de famille, je lègue tout ce que je possède à la Société de Biologie, où j'ai toujours trouvé bon accueil et sympathie depuis le jour où j'en ai été membre. Je crois fermement que c'est le meilleur usage social à faire du peu de bien que je laisse environ 2000 francs de rente." (£80 a year).

DR. WALTER DICKSON, R.N., the author of "The Antarctic Voyage of H.M.S. *Pagoda*," and several works on naval hygiene, died on the 9th inst. at the age of seventy-three.

BY the recent death of Lieut.-Colonel Garrick Mallery, in his sixty-fourth year, the U. S. Bureau of Ethnology has lost one of its chief ornaments. The results of his important researches into the sign and gesture language of American aborigines occur in the current annual report of the Bureau.

THE *Times* reports a severe earthquake and volcanic eruption at Ambrym, an island in the New Hebrides group. The disturbance is said to have occurred on October 15, when several severe shocks were felt throughout the whole island. Immediately afterwards the volcano, which is 2500 feet high, was observed to be in active eruption. The lava destroyed the native villages on one side of the island, and a large number of natives sought refuge on board H.M.S. *Dart*, which was cruising off the coast. Considerable damage appears to have been done in a large portion of the island.

THE Christmas course of lectures, adapted to children, at the Royal Institution, will be delivered by Prof. J. A. Fleming, F.R.S. The subject will be "The Work of an Electric Current," and the first lecture will be delivered on Thursday, December 27, at three o'clock.

FOR several weeks the weather over the British Isles has been very unsettled, but no gales of serious importance had been generally experienced until Sunday night, when a deep barometric depression reached our south-west coasts from the Atlantic, accompanied with very heavy rainfall in the south and west; the amount measured at Scilly during twenty-four hours ending 8 a.m. on the 12th instant amounted to over three inches, or nearly the average fall for the month, while at Hurst Castle, on the Hampshire coast, the fall exceeded two inches. The central area of the storm passed the whole length of the English Channel, and crossed the North Sea during Monday night, strong northerly gales being experienced in the rear of the disturbance, accompanied with thunderstorms, hail, and more heavy rain, the amount measured in London on the 13th instant being about 0·75 inch. A very rough sea was experienced in the English Channel and in the Irish Sea. This disturbance was followed by another which approached our extreme north-west coasts on Tuesday night, causing strong gales over all parts of the country, and very heavy rain in the west. The temperature has been from 4° to 6° above the mean; during the week ended the 11th instant the highest maxima recorded were 61° in the Channel Islands, and 60° in the south of England, and the lowest minima fell to 29° in the south-west of England, and to 32° in the Midland Counties.

PROF. GUIDO CORA, of Turin, will, on his approaching birthday, December 20, be presented by his former students with "a special mark of esteem and affection" in the form of a memorial in recognition of the twenty-fifth anniversary of his first published paper. It is well known that he founded and has maintained the geographical journal, *Cosmos*, at his own expense. In order to give his many scientific friends an opportunity of sharing in the general recognition of Prof. Cora's labours, Prof. Paul Revelli, 12 Via Galliari, Turin, is prepared to receive any written "sentiment," portrait, drawing, or signature for the memorial volume. The date up to which such tokens of respect may be sent is extended to March 31, 1895.

DR. DONALDSON SMITH, who left London early this summer to attempt to reach Lake Rudolf from the north-east, has been able to send letters home from a position in 7° 11′ N., and 42° 11′ E., dated early in September. He had formed a caravan at Berbera, started with more than a hundred camels, and travelled south-westward through an unmapped country, of which he has made a running survey. At Turfa he reached a great river, which he believes to be the Erer, and to be continuous with the Webi Shebeli. Being unable to cross, he spent a week in following the course of this river, thirty miles of which he has mapped; and on his return he succeeded in finding a ford, where the caravan crossed with much difficulty. The country was very thinly peopled, on account of wars between the Gallas and Ogadams, but some natives were found to carry letters to the coast, a task which they must have performed very expeditiously. Dr. Smith has made large collections of the fauna and flora of the region traversed, and has had some thrilling adventures with big game. His men were doing well, and he was confident of success in his journey, although the time necessary to complete it appeared likely to be rather longer than was originally expected.

THE death is announced of Colonel R. Y. Armstrong, C.B., F.R.S., late of the Royal Engineers. He was born in 1839, and was the son of the late Rev. W. Armstrong, of Cairy, County Sligo.

IN the last number of the *Scottish Geographical Magazine* Mr. W. S. Anderson, of the Scottish Marine Station, discusses the relative merits of the methods for determining the density of sea-water by means of hydrometers and by direct weighing. He shows that if the temperatures of water, instrument, and air are in equilibrium, and the observations made on land, the *Challenger*-type hydrometer yields results of equal value with those of Sprengel tubes, provided the mean of a large number of observations is taken. At sea the hydrometer is less satisfactory. Mr. Anderson throws discredit on previous work in this direction, and assumes that the work of some earlier observers showed large discrepancies on account of the scale of the hydrometer being read from the wrong end. Unfortunately, he does not make any reference to the place where this work is published. By the use of a very large hydrometer admitting of the detection of extremely delicate differences in density, Mr. Anderson satisfied himself that capillarity has no perceptible effect upon the accuracy of the readings. By a series of observations at different temperatures he has been able to construct new tables for the reduction of observed densities to standard temperature, and for the calculation of the function D, which is the difference of density between the sample and pure water divided by the number of grammes of chlorine per litre, a function to which considerable importance is now attached in the discussion of the relative differences between samples of sea-water.

OUR excellent contemporary, *The Engineering Magazine*, commenced a "Review of the Industrial Press" in the October number, and an index of current technical literature. The object of this review and index is to give concisely-written notices of the most important articles of the month; and to supply a carefully classified index to all the articles published currently in the scientific and industrial press of the United States and Great Britain. An entirely new feature is the establishment of a department to supply all or any portion of any article reviewed or indexed. That technical journalism has grown to proportions and importance which warrant such a development, is a fact at which we can all rejoice.

OBSERVATIONS on the variations in level of well-water have been made for the last three years at the Observatory of Catania in Sicily, and the first results are described in a paper by A. Riccò and S. Arcidiacono (*Boll. mens. dell'Acc. Cioenia di Sci. Nat. in Catania*, fasc. 37, June 10, 1894.) They classify the movements into progressive, annual and accidental, subdividing the latter into meteoric and geodynamic. The accidental variations of geodynamic origin consist of small abrupt changes of level, generally downwards, which frequently correspond to movements of the ground. Shortly before the eruption of Etna in 1892, and for several months after, the changes in level of the water-surface were extremely irregular. From June 1, to December 31, 1892, corresponding to thirty-nine groups of earthquakes, there were abrupt changes of level within twenty-four hours in twenty-one cases; there were also fifty small but marked changes coinciding with strong oscillations of the tromometer. Somewhat similar observations have been made in Wisconsin, by Prof. F. H. King (U. S. Dep. of Agri. Weather Bureau, *Bull.* No. 5). Here the shock was imparted by heavily-laden trains passing less than fifty yards from the well; but the surface of the water invariably rose, sometimes as much as one-tenth of an inch, returning to its former level after a few seconds.

AT a recent meeting of the Academy of Science of Amsterdam, Herr C. H. Wind read a note on the Kerr phenomenon. The author breaks up the electric current into two parts—a current of conduction and a displacement current—and to these attributes, as Lorentz has done, the Hall effect. He supposes, however, that the electromotive force which constitutes the Hall effect is different for the two constituents, while Lorentz supposes them to be equal. The introduction of this hypothesis into the calculations of Van Loghem does not alter the general form of the results, but has the effect of giving expressions for the phase and the amplitude of the magneto-optic component which differ by a constant quantity and a constant angle from the old values. In this way the difference of phase discovered by Sissingh is explained; and from the observed value of this difference of phase the ratio between the intensity of the Hall effect for the displacement and conduction currents can be calculated, and then from observations of the amplitude the value of each of these can be found. From the calculations made by the author, it appears that the values thus obtained are of the same order as those got by direct observation of the Hall effect, if we suppose that the specific resistance of metals for periodic currents of extreme rapidity is greater than for continuous currents. This view is further supported by other calculations which have been made by the author. The paper concludes with a comparison between the above theory and the theories propounded by Thomson, Goldhammer, and Drude.

IN No. 38 of the *Sitzungsberichte* of the Berlin Academy, Prof. Goldstein gives an account of a curious effect which the cathode rays exert on the colour of certain salts. If potassium chloride be made to phosphoresce in a radiation-tube, it quickly assumes a strong heliotrope shade, and eventually becomes bright violet. On heating, the colour changes to blue, and at high temperatures the salt becomes white. The same series of colour-changes may be obtained with this decolourised salt, and also with naturally occurring potassium chloride or sylvine. Several haloid salts of the alkali metals were examined, and with the exception of cæsium and rubidium chlorides all gave after-colours. The chlorides of barium and strontium gave no after-colours. In ordinary air the colour disappears the more quickly the more soluble the salt. The colour of lithium chloride fades almost immediately; the blue colour of sodium chloride lasts about a day. In contact with water the salts at once lose their colour. In a vacuum or in dry air the deep blue colour of lithium chloride has now lasted for two months without apparent change. The colour of potassium chloride gradually fades and completely disappears in about a week; the behaviour of most of the salts is like that of potassium chloride. The cause of these phenomena is unknown. The salts were as pure as could be obtained. Electrodes of different materials gave the same results. The radiation-tubes contained, of course, a little mercury vapour, but none of the known compounds of mercury with the constituents of the salts have the colours above described. Chemical decomposition is unlikely, since the coloured salt gradually changes into its original condition. The author inclines to the view that during phosphorescence the particles of the salt have been made to take up positions and motions differing from those of the unaltered substance, and that a physical modification of the salt has thus been brought about.

SOME efforts have again been made in France to overcome the air resistance which a locomotive encounters when running at a high rate of speed. *La Nature*, for October 27, contains a very interesting article by M. Max de Nansouty, descriptive of the experiments of M. Ricour, originally made in 1887. In these, inclined planes were placed in front of the engine, and by adopting this means, making the slanting planes four in three, and filling up the spokes of the wheels, the resistance was diminished by one half. This resulted in a notable increase of useful work, and an economy of ten per cent. on the coal consumption. The results are so satisfactory that M. Ricour has fitted his apparatus on forty engines belonging to the Paris-Lyon-Mediterranée Railway, for general traffic. Similar experiments were carried out in 1890 by M. Dresdouit, chief engineer to the State railways, and they were of more prolonged character. The engines in this case were ran 300,000 kilometres, and by means of this apparatus they saved six to eight per cent. in coal consumption, and sometimes as high as twelve per cent. M. Max de Sonty tells us, however, "il est vrai que le chauffeur et le mécanicien étaient excellents." A few other experiments were tried with seemingly the same satisfactory results. The main point, however, that, on an average, a benefit of four to five per cent. is obtained by the use of these inclined planes, and it is asserted that this is more than the saving obtained from locomotives with compound and other systems. If the statement be true, our locomotive superintendents had better take heed, as nothing has yet been done in this direction. We are not told, however, how the apparatus behaves with a side wind.

WE have received a catalogue of botanical works offered for sale by Messrs. Dulau and Co. The books refer to the anatomy, morphology, and physiology of plants.

THE *Journal* of the Sanitary Institute, vol. xv. part iii., contains the addresses delivered at the Congress held at Liverpool in September. Dr. J. F. J. Sykes contributes a report of the proceedings of the International Congress of Hygiene, Budapest.

MESSRS. BLACKIE AND SON have published the seventh part of Kerner and Oliver's "Natural History of Plants." The new part, which is just as admirable as the previous ones, concludes the section on climbing plants; and deals with erect foliage stems; the resistance of foliage stems to strain, pressure, and bending; the floral stem. It also contains the beginning of the section on the forms of roots.

"ELECTRIC Lighting and Power Distribution," by Mr. W. Perren Maycock, published by Messrs. Whittaker and Co., has reached a second edition. The book is described as "an elementary manual for students preparing for the preliminary and ordinary grade examinations of the City and Guilds of London Institute." It is profusely illustrated and clearly written, and is altogether a good introductory text-book of technical electricity.

DR. OSCAR GRULICH has prepared a history of the foundation and growth of the K. Leopoldinisch - Carolinischen Akademie der Naturforscher at Halle. The volume is dedicated to Halle University, which celebrated its bi-centenary this year. The first president of the Academy was J. J. Baier, who held the office from 1731 to 1735. Many eminent investigators have occupied the president's chair since then, and Prof. Dr. Knoblauch has held it since 1878. Dr. Grulich's book chiefly deals with the famous library and scientific collections of the Academy.

THE third volume of Sir David Salomons' "Electric Light Installations," dealing with the applications of electric energy, has been published by Messrs. Whittaker and Co. It will be remembered that the original work, "Electric Light Installations and the Management of Accumulators," was in one volume, and it was not until a seventh edition was demanded that the division into three volumes took place. The present volume is mainly concerned with the mechanical details which interest the electrical engineer, and the workmen engaged in electric installations, and to such we cordially recommend it.

Science Progress for November contains five articles of technical interest and importance. Dr. A. D. Waller, F.R.S., describes the state of knowledge of inhibitory phenomena; Mr. J. W. Rodger contributes the third of a series of articles on the new theory of solutions. Recent researches in thermal metamorphism are described by Mr. Alfred Harker. Mr. S. H. Burbury, F.R.S., discusses Dr. H. W. Watson's "Treatise on the Kinetic Theory of Gases" and a communication made by Prof. Tait to the Royal Society of Edinburgh, "On the Foundation of the Kinetic Theory of Gases." Finally, Prof. A. C. Haddon gives a bibliography of the ethnography of British New Guinea.

THE "Division of Microscopy" of the United States Department of Agriculture is publishing a very useful series of small manuals under the title "Food Products." The first three numbers deal almost entirely with edible and poisonous fungi, with directions for their identification, and for the culture and preparation for the table of the edible species. They are illustrated by excellent coloured and uncoloured plates. It is a significent illustration of the wide distribution of the lower as compared with the higher forms of vegetable life, that every one of the twenty-four edible and twelve poisonous species of fungus here described is a familiar European species. The letterpress is written by Dr. Thomas Taylor, chief of the Division of Microscopy.

THE Meteorological Council have just issued a volume containing the meteorological observations made at stations of the Second Order, for the year 1890. Such observations have been published in a more or less complete form since 1866, and the present volume contains returns from sixty-eight stations, part of the information being obtained from the English and Scottish Meteorological Societies. A map shows the distribution of the stations, which are well distributed over the United Kingdom, although in some districts, especially in the West of Ireland, there appears to be difficulty in obtaining good observers. In addition to daily observations at many stations, the work contains carefully prepared monthly and yearly summaries, and a table showing the number of hours of bright sunshine for each month at those stations which are provided with sunshine recorders.

IN 1815 there was published in Philadelphia the second edition of a "Geographical, Historical, and Commercial Grammar," by William Guthrie. This edition contained an account of North American Zoology, by George Ord, which was by far the most complete and accurate that had appeared. Prof. Baird, in his work on the mammals of North America, refers frequently to this contribution to Guthrie's Geography, and his citations have helped to establish its importance. The Academy of Natural Sciences, Philadelphia, being desirous of rescuing Ord's work from extinction, determined to reprint it. After considerable difficulty, a copy of Guthrie's Geography was found, containing marginal pencil notes by Ord, on the zoological portion. This section of the book has now been reprinted, with the notes, and to it Mr. S. N. Rhoads has added an appendix on the more important scientific and historic questions involved. The reprint will be heartily welcomed by students of the systematic zoology of America.

HELMHOLTZ remarked, in the autobiographical address delivered on the occasion of his jubilee: "Many a time when the class was reading Cicero or Virgil, both of which I found very tedious, I was calculating under the desk the path of rays in a telescope, and I discovered, even at that time, some optical theorems, not ordinarily met with in text-books, but which I afterwards found useful in the construction of the ophthalmoscope." The enquiring student of the present time has no difficulty in finding optical theorems not referred to in the text-books in common use, for in most elementary manuals on optics, the sections appertaining to lenses and mirrors are treated inadequately. It ought to be recognised, however, that a thorough knowledge of lenses and mirrors is the all-important point of optics. To supply the deficiency of text-books in this respect, Prof. R. C. Bodkin has prepared a little pamphlet—"On Lenses and Mirrors, and the Automatic Image-Finder" (John J. Griffin and Sons)—in which he simplifies the study of lenses and mirrors, and deduces the construction of microscopes, telescopes, &c., from first principles. The image-finder referred to in the title is an ingenious piece of apparatus for illustrating the directions of the rays forming the image of an object.

WE do not often receive a catalogue of educational books, scientific and technical treatises, and works of general knowledge prepared for use in Chinese schools. Therefore we have looked with unusual interest through such a catalogue received from "the well-known Chinese Scientific Book Depôt, 407 Hankow Road, Shanghai." According to the title-page of the catalogue, the works described have been translated or written by Dr. John Fryer; and as there are nearly two hundred of them, covering the whole fields of natural and physical sciences, we confess to a reverential feeling for Dr. Fryer's marvellous industry and encyclopædic knowledge. The translations are mostly based upon standard English or American educational books, and are arranged into five series. There is the "outline" series, for general reading and elementary instruction; the "handbook" series, for more advanced students; the "temperance physiology" series, the "magazine" series, adapted for school reading books; and the "Imperial Government" series, consisting of treatises, which together form a valuable encyclopædia. As the avowed object in publishing the works is the higher education and intellectual enlightenment of the Chinese nation, we echo the hope that the use of the translations will continue to extend wherever instruction in scientific subjects is given in the Chinese language.

THE additions to the Zoological Society's Gardens during the past week include two White-shafted Francolins (*Francolinus leucoscepus*) from North-east Africa, presented by Lord Lilford; two Nilotic Crocodiles (*Crocodilus niloticus*) from West Africa, presented by Mr. J. A. McDiarmid; four Hispid Lizards (*Agama hispida*) from South Africa, presented by Mr. J. E. Matcham; an Australian Fruit Bat (*Pteropus poliocephalus* from Australia; a White-fronted Amazon (*Chrysotis leucocephala*) from Cuba, purchased.

OUR ASTRONOMICAL COLUMN.

A NEW VARIABLE STAR OF THE ALGOL TYPE.—Dr. E. Hartwig announced in the middle of September that the star B.D. + 15°·3311 (R.A. 17h. 53m. 36s., Decl. + 15° 8′ 47″·2, 1900) was a variable of the Algol type. He afterwards determined the period to be 3d. 23h. 49m. 32s.·7. (*Astro. Nach.* 3260). It appears, however, that Dr. S. C. Chandler discovered the character of the star's variability at the end of July, and communicated his discovery to several other observers, who confirmed it. The star was assigned the notation 6442 Z. Hercules about the middle of August, the period having previously been determined as 3d. 23h. 50m. Prof. Dunér has found that the minima follow each other at unequal intervals of forty-seven and forty-nine hours. There appears to be a secondary minimum which occurs a few hours previous to the time midway between two successive primary minima.

THE POLAR CAPS OF MARS.—Several sketches of Mars, made at the Juvisy Observatory, by M. Antoniadi, accompany a paper by M. Flammarion in the current *Comptes-rendus*. The figures show clearly the slow diminution of the snow-caps of Mars during the summer of the planet's southern hemisphere. The summer solstice occurred on August 31, and the planet was kept under observation from June 1 to November 1. The following are the results of the measures of the diameters of the cap at the south pole of Mars, on different dates:—

Dates.	Areocentric arc.	Diameter in kilometres.
June 1	65°	3900
,, 15	50	3000
July 1	42	2520
,, 15	35	2100
August 1	30	1800
,, 23	15	900
September 27	11	660
November 1	5	300

ENCKE'S COMET.—Prof. M. Wolf has found Encke's comet upon a photograph taken on October 31, that is, a day before Dr. Cerulli's observation, noted last week (*Astr. Nach.* 3262). The comet has been observed by M. Perrotin, and is said to be at the extreme limit of visibility of the twenty-eight-inch refractor of the Nice Observatory.

STATISTICAL ACCOUNT OF FRENCH FORESTS.[1]

M. DAUBRÉE, the Director of the French Forest Department, has recently published a statistical account, up to the end of 1892, of the French forests which are managed by that department; and as these forests, especially in the northern and central parts of France, greatly resemble those which might be grown in the United Kingdom, and of which some badly-managed examples are still to be found, a short notice of this work will be interesting to those who wish to know what are the possibilities of economic forestry at home.

The areas of the forests in question are as follows:—

	Acres.
Belonging to the State	2,691,165
,, communes and public establishments (hospitals, colleges, &c.) ...	4,738,637
Total	7,429,802

Or 11,609 square miles, one-eighteenth of the total area of France, which is about 207,100 square miles.

No account is here taken of the private forests in France, which contain about 20,813 square miles, so that the area of all the forests in France is 32,422 square miles, or 15½ per cent. of the area of the country.

Of the 7½ million acres of forest managed by the State, 18 per cent. of the State forests and 3·6 per cent. of the communal forests are classed as unproductive or not stocked with trees.

A larger proportion of the State forests is unproductive because the State is constantly acquiring waste lands in order to prevent denudation of mountains by torrents, or the encroachment of sandy dunes; whilst land belonging to the communes, &c., which is not fit for reafforesting, is not generally handed over to be managed by the State Forest Department.

Twenty excellent maps are attached to the report, and are differently shaded so as to show the distribution of the forest area among the different *départements*, according to ownership; mode of management (coppice, coppice-with-standards, high-forest); annual degrees of productiveness—in material (cubic metres per hectare); in money (francs per hectare)—and also in oak and coniferous timber.

From these maps and the statement which precedes them, it may be readily seen that the State forests are most extensive north of Lyons, and especially in Lorraine, Bourgogne, Isle de France, Normandy, le Bourbonnais, and that in these provinces there are scarcely any unproductive areas, which chiefly occur in the south of France. The communal forests are also chiefly in the east of France, or bordering on the Pyrenees and in Corsica; this distribution depends on political and not on natural causes, for the climate of the west of France is very favourable to forest growth, and this region contains some magnificent State forests and large areas of forests in private hands. As regards the mode of treatment, the State forests are distributed as follows:—

	Percentage of total area.
Simple coppice	2·5
Coppice-with-standards	29·2
,, under conversion to high forest...	16·8
High-forests	51·5

The simple coppice belonging to the State is chiefly situated in the south, where the State shares in the produce with certain communes, or the inhabitants have rights to fuel, which prevent any improvement in their treatment, and they are generally composed of *Quercus Ilex*, which yields tanning bark, and firewood rather than timber.

Coppice-with-standards is applied to large forest areas bordering on Belgium, and to another series of State forests stretching from the Jura towards Paris. These forests are generally situated near large towns or the northern coal mines, and find a ready sale for their somewhat branchy timber and underwood, as building material, pit-props, firewood, &c., provided their rotations are long enough to exclude a large supply of charcoal wood, for which the demands are being gradually restricted.

A large area of coppice-with-standards, which is remote from large towns and the coal mines, is being converted into high forest, to increase the supply of timber as compared with firewood.

[1] Statistique des forêts soumises au régime forestier, Année 1892. Extrait du Bulletin du Ministère de l'Agriculture. Paris: *Imprimerie Nationale*, 1894.

More than half the area of the State forests is already under the high-forest treatment, and consists chiefly of highly-productive silver-fir and beech forest in the Vosges; forests of *Pinus Laricio* and *Pinus Pinaster* in Corsica, which only yield poor returns on account of the frequency of forest fires; beech forests in Normandy with a small proportion of oak, and extensive oak forests on the Loire and its tributaries, where beech is kept subservient to the principal species. The maritime pine forests of the Landes and Gironde yield large quantities of resin and turpentine, as well as inferior timber, pit-props, &c.

The communal forests are distributed as follows:—

	Percentage of area.
Simple coppice	14·7
Coppice-with-standards	53·2
,, under conversion to high-forest ...	1·0
High-forests	31·1

The communal simple coppice areas chiefly supply fuel to villagers, and consist mainly of *Quercus Ilex* in the south, and of common oak and other species in the Ardennes and lower slopes of the Alps, near the villages and below the coniferous forests of the higher zones.

Coppice with-standards is the commonest mode of management of communal forests, and is distributed chiefly in the temperate regions of hills and plains of the north-east of France, and little of this area is being converted to high-forest, as the people do not care sufficiently for the benefit of futurity to sacrifice a considerable part of their present revenues.

The high forests belonging to communes, &c., are chiefly situated in the Vosges, Jura, Alps, Pyrenees, and in Corsica, consisting chiefly of conifers mixed with beech.

Detailed tables are given regarding the yield of the forests in material and money.

Thus the production of the forests during the year 1892 was as follows:—

—	State forests.	Communal forests, &c.
	c. feet	c. feet.
Wood	96,051,592	169,275,133
	cwt.	cwt.
Cork	2,300	6,100
Bark for tanning ...	283,000	463,000
Crude resin	37,800	16,300
Total value ...	£846,144 at 25 fr. = £1	£1,321,804

The average annual production per acre of the wooded area of the forests is as follows:—

	c. feet.	s.	d.
State forests	43½ ...	9	5
Communal and other forests...	37 ...	5	10

It is evident that the State forests yield more wood, and of a better quality, than the communal forests.

Leaving out the Departments of the Seine and Corréze, where the production in quantity of material and money is abnormally high, the areas of State forests in these Departments being inconsiderable, the forests of the Vosges head the list with an annual yield of 7·136 c.m. per hectare, equivalent to 101 c. feet per acre, and worth £1 3*s*. 4*d*.

This return is exceeded in value, though not in quantity, by the forests of the Doubs, where there is much oak grown as well as silver-fir, and the yield is 5·867 c. metres per hectare = 84 c. feet per acre, and worth £1 7*s*. 5*d*. an acre.

The productiveness in different classes of material of the different forests are as follows:—

STATE FORESTS.

Broad-leaved Species.

		Percentage of yield.
Timber	Oak 20 in. in diameter and above ...	5
	Do. less diameter	5
	Other broad-leaved species	6·1
Poles		3·8
Firewood		57·1

Conifers.

Timber	Exceeding 20 in. in diameter... ...	9·4
	Less than ,, ...	5·3
Poles		0·6
Firewood		7·7

The proportions of the yield of broad-leaved and coniferous timber is as follows:—

	Percentage.
Broad-leaved...	77
Coniferous	23

It is noted that the broad-leaved species yield 74 per cent. of firewood, while the conifers only yield 33 per cent.

In the communal and other forests the production is as follows:—

	Percentage.
Broad-leaved	81·3
Coniferous	18·7

And the percentage of firewood in the former case is 86 per cent., whilst for the coniferous forests it is 25 per cent. These forests are less productive in timber, and especially in timber exceeding 20 inches in diameter, than the State forests, which accounts for their reduced money return.

If we omit the large sum of £99,300 spent in 1892 on planting-up dangerous mountain sides and regulating the beds of mountain torrents, and £8,400 spent on fixing shifting sands, the cost of maintenance of the whole of the productive forests referred to in 1892 was £397,080, or about 1*s*. 2*d*. per acre, which must therefore be deducted from the yield of the forests to determine their net revenues per acre.

The following is a complete statement of the French forest charges for 1892:—

	£
Establishment	231,800
Forest schools	6,880
Works of improvement in the forests ...	58,000
Mountain *reboisement*	99,300
Fixing shifting sands	8,400
Working plans and fellings	16,000
Management of *chasses* which are not leased	2,000
Taxes	72,400
Law and other charges	10,000
	£504,780

Of this amount £41,268, or about 2*d*. an acre, is refunded to the State by the communes and public establishments for the management of their property. W. R. FISHER.

THE PROPERTIES OF LIQUID ETHANE AND PROPANE.

A COMPREHENSIVE study of the properties of these primary hydrocarbons in the liquefied condition has been made by Dr. Hainlen in the laboratory of Prof. Lothar Meyer at Tübingen, and an account of his work will be found in the current issue of *Liebig's Annalen*. Owing to the greater ease with which it undergoes liquefaction, propane was first investigated. The hydrocarbon was obtained in a state of purity by means of the admirable method of preparation discovered in the same laboratory in the year 1883 by Köhnlein, which consists in heating propyl iodide with aluminium chloride in a sealed tube to 130°. After subjection to this temperature for twenty hours the tube was allowed to cool, and subsequently placed in a freezing mixture; while immersed in the latter it was found practicable to open it without danger or loss, the accumulated gas being readily transferred to a gas-holder over water.

In order to determine the boiling-point of propane, the purified gas was first condensed to the liquid state in a U-tube surrounded by solid carbon-dioxide. It was then transferred to the special boiling-point apparatus by evaporation and recondensation, the last traces of impurities being eliminated by this process of repeated distillation. The special apparatus consisted of a glass tube closed at the lower end, furnished with a side tube for the entrance of the gas, and with a stopper at the open end perforated for the passage of an exit-tube and a thermometer. The upper half of the cylinder was surrounded by solid carbon-dioxide, and the lower portion was protected by a mantle of badly-conducting felt. Upon the entrance of the gas the air was expelled by the exit-tube, and the gas which condensed in the upper portion of the cylinder collected in the lower portion. When the protecting mantle was removed the relatively warm air soon promoted ebullition, and the escaping vapour was as rapidly recondensed in the cooled upper portion of the cylinder, and fell back into the lower. If the hand were brought into the proximity of the cylinder, the boiling became most vigorous. At first propane usually boils irregularly, quiescent intervals being succeeded by almost explosive ebullition; but after a short time the formation of vapour becomes perfectly regular, and a mercury thermometer dipping in the liquid registers a temperature of $-38°$. After comparison of the latter with an air thermometer, the correct temperature of the boiling-point of propane is found to be $-37°$ at 760 m.m. pressure.

Propane may safely be sealed in strong glass tubes after condensation by means of solid carbon dioxide, and thus preserved in the liquid state. It is a perfectly colourless liquid, but much more viscous than liquid carbon dioxide. The critical temperature was determined by use of such a tube half filled with the liquid. The tube was immersed alongside a thermometer in a bath of liquid paraffin, furnished with a suitable stirrer. Upon heating the apparatus to 101° the liquid meniscus commenced to become hazy, and the distinction between gas and liquid became less and less pronounced until at 110° all trace of it had disappeared. Upon cooling, the well-known nebulosity was observed at 102°, and this temperature is considered to be a close approximation to the critical temperature of propane.

The vapour pressures of propane for different temperatures up to 12°·5 were determined by enclosing a quantity of the liquefied hydrocarbon in one limb of a U-tube and dried air in the other limb, the two being separated by means of a short column of mercury. The closed apparatus was then cooled to various temperatures in suitable baths, and the vapour pressures calculated from the amount of compression of the air column. The vapour pressures for temperatures superior to the ordinary were determined by use of the Caillétet apparatus and spring manometer. The following table represents a summary of the results:

Temperature.	Pressure in atmospheres.	Temperature.	Pressure in atmospheres.
$-33°$	1·8	$+1°$	5·1
$-19°$	2·7	$+5°·5$	5·9
$-15°$	3·1	$+12°·5$	7·1
$-11°$	3·6	$+22°$	9·0
$-5°$	4·1	$+53°$	17·0
$-2°$	4·8	$+85°$	35·0
		$+102°$	48·5

The critical pressure of propane corresponding to the critical temperature of 102° is consequently 48·5 atmospheres.

Dr. Hainlen has also determined the density of liquid propane at several temperatures. It is 0·536 at 0°, 0·524 at 6°·2, 0·520 at 11°·5, and 0·515 at 15°·9, compared with water at 4°.

An investigation of the properties of liquid ethane upon similar lines naturally presented greater difficulties, on account of the further removal of its boiling-point from the ordinary temperature. The pure gas cannot be so conveniently prepared by the method of Köhnlein, as the sealed tubes frequently explode with great force. It was therefore obtained by the well-known method of Gladstone and Tribe from ethyl iodide and the zinc-copper couple. A mixture of ether and solid carbon dioxide is insufficient to effect liquefaction of the gas, but liquid ethylene was found to bring about the necessary reduction of temperature, which latter was measured by means of a copper-silver thermo-element. Liquid ethane in the pure state is perfectly colourless.

The boiling-point of ethane was determined as in the case of propane, the upper part of the apparatus, however, being surrounded by the liquid ethylene instead of solid carbon dioxide. The ethylene was prevented from vapourising rapidly by allowing the extremely cold vapour produced by the evaporation to pass through an outer cylinder, and thus to act as a protective cold bath. The ethane was first cooled by means of ether and solid carbon dioxide before admission into the boiling-point apparatus, after which it was found to be rapidly condensed by the colder ethylene. One end of the thermo-element was immersed in the accumulated liquid instead of a thermometer. The temperature of the liquid when in regular ebullition, produced by removing the cap protecting the lower half of the cylinder, was found to be $-89°·5$ at 735 m.m. pressure.

Liquid ethane cannot be sealed in a glass tube without considerable danger. Hence the determinations of vapour pressure and density were effected by the use of a modified Caillétet compressing apparatus and spring manometer. The various temperatures were obtained by surrounding the narrow thick-walled glass tube in which the liquid was produced by suitable baths. The critical temperature at which the curious cloudy appearance was observed, just before the complete disappearance of the liquid meniscus, was found to be 34°·5, and the corresponding critical pressure 50 atmospheres. The meniscus becomes hazy at 32° and only disappears completely at 40°, so that the critical temperature, as in the case of propane, does not appear to be so sharp as with many other liquids of low boiling-point. The following table represents the vapour pressures for a few intervals of temperature.

Temperature.	Pressure in atmospheres.	Temperature.	Pressure in atmospheres.
$-31°$	11	0°	23·3
$-20°$	14·5	$+15°$	32·3
$-11°$	18·3	$+34°·5$	50

Prof. Dewar in 1884 determined the critical temperature and pressure of ethane, and gave them as 35° and 45·2 atmospheres. M. Caillétet had previously stated that at $+4°$ the gas exerted a pressure of 46 atmospheres. Prof. Dewar's numbers are now found to be in close accordance with Dr. Hainlen's results, and the older statement of M. Caillétet must therefore be taken as founded upon an error.

The density of liquid ethane was found to be 0·446 at 0° and 0·396 at $+10°·5$.

It may be interesting to compare the facts now established with reference to ethane and propane, with those previously well ascertained for marsh gas and for normal butane.

	Boiling point.	Critical temperature.	Critical pressure.	Density in liquid state.
			atm	
Methane CH_4	$-164°$ (Olszewski)	$-81°·8$ (Olszewski)	54·9	0·415 at $-164°$
	-160 (Wroblewski)	$-95·9$ (Dewar)	50	
Ethane C_2H_6	$-89·5$ at 735 m.m.	$+34·5$	50	0·446 at 0
Propane C_3H_8	$-37·0$ at 760 m.m.	$+102$	48·5	0·536 at 0
n-Butane C_4H_{10}	$+1$	—	—	0·60 at 0 (Ronalds 1865)

If the above boiling-points are represented graphically along with those of the higher normal paraffins, molecular weight or the number of carbon atoms being taken as abscissæ and boiling-point as ordinates, a perfectly regular curve is obtained, slightly concave towards the axis of abscissæ, which very clearly indicates the dependence of the boiling-point upon the molecular weight.

A. E. TUTTON.

THE BRITISH CENTRAL AFRICA PROTECTORATE.

MR. H. H. JOHNSTONE opened the session of the Royal Geographical Society on Monday evening with a paper on British Central Africa, of which he is administrator. He contrasted the condition of the country ten years ago with what it is now, explaining how the Mission schools, the Scottish planters, and the Sikh police had produced changes in the manners, productions, and means of transport of the whole region, and had succeeded in effectually repressing the slave trade. A survey of the Protectorate has been in progress for the last three years, and the map is beginning to acquire some firmness of outline. The great advantage of the Protectorate over the surrounding districts lies in the greater proportion of high land over low swampy country. Roughly speaking, about four-fifths of its land-surface is 3000 feet and upwards above the level of the sea, and about one-fifth is between 5000 and 10,000 feet. The immediate result of this elevation of the land is the prevalence of a much cooler climate than is usually found in Central Africa so near the equator. There are portions of British Central Africa where the heat is never oppressive, even in the hot season, and where in the cold season bitter frosts prevail. Unfortunately, it is impossible to reach this delectable land from the coast without traversing the hot and unhealthy valleys of the Zambezi and Shire.

There is an average rainfall of 55 inches throughout the Protectorate, but it is not altogether uniform in character, some districts receiving about 75 inches, and others not more than 35 inches. Still, it is decidedly a well-watered country, endowed with many perennial streams, only a small number of which dry up in the height of the dry season. Consequently, it is a land which can almost everywhere be irrigated during the dry season, and can thus grow a continual succession of crops. The water is almost everywhere wholesome to drink.

The great attraction of the country lies in its beautiful scenery, in its magnificent blue lakes, its tumultuous cascades and cataracts, its grand mountains, its golden plains and dark green forests. A pleasant and peculiar feature also of the western portion of the Protectorate is the rolling grassy downs, almost denuded of trees, covered with short turf, quite healthy, and free from the Tsetse fly; these no doubt will in the future become actual sites of European colonies, districts in which Europeans can rear their children under healthful conditions.

The lofty plateau of Mlanje is a little world in itself, with the exhilarating climate of Northern Europe. These plains and valleys are gay with blue ground-orchids, with a purple iris, and with yellow everlasting flowers. Here and there great rocky boulders stand up in stern relief against the velvet turf, and out of these elevated plains again rise other mountains, gloomy in aspect and remarkably grand in outline. The forests, on closer inspection, turn out to be mainly composed of the handsome conifer *Widdringtonia Whytei*.

No one has succeeded in reaching the highest summit of Mlanje. Mr. Johnston ascended about as far as 9300 feet, and, estimating that there were fully 700 feet more of ascent, approximately fixed the highest point at 10,000 feet. The ascent of this high peak is rendered very difficult by the enormous size of the boulders with which it is strewn. The whole mountain mass of Mlanje probably occupies, with its outlying peaks connected by saddles, an area of 1600 square miles, of which 200 square miles consist of these level or gently undulating plateaux, admirably suited for European settlements. Many of the salient features of Mlanje are repeated in the striking mountains of Nyasaland, with the exception of the cedars, which, however, are reported to exist on one or two of the highest peaks of Zomba, but have never been seen elsewhere.

The low plains surrounding Lake Nyasa and bordering the rivers offer a sharp contrast to the plateaux. Zebras, hartebeests, water-buck, pallah, roan antelopes, and reed-buck may be found in numbers, often dwelling gregariously together on these hot plains; and a few vultures, eagles, kites, and Marabout storks wheel and float overhead in the dazzling bluish-white sky, on the look-out for offal. The sable antelope, the eland, the kudu, and the bush-buck seem to prefer the sparsely forested hill-slopes to the flat plain, where there is usually much less cover. The rhinoceros still ranges over these plains, and wallows in the stagnant pools of the half-dried rivers. The heat prevailing on the plains in the summer-time is very great—almost overpowering—but in the winter and spring the air is exhilarating.

The British settlements have now a settled and comfortable appearance, with uniformed native policemen and trained natives from the Mission schools working as printers and even as telegraph operators at Blantyre. The most interesting feature in the neighbourhood of these settlements at the present time is the coffee-plantation, which, to a great extent, is the cause and support of their prosperity. The variety which is cultivated in the Shire highlands was actually introduced from Scotland, having been derived from a small plant sent from the Edinburgh Botanical Gardens to Blantyre about sixteen years ago. From this plant the greater part of the five million coffee-trees now growing in this part of Africa are descended, while the original mother tree is still alive in the Mission grounds at Blantyre. The climate and soil of Nyasaland would seem to suit the coffee-tree to perfection, and the crops given are unusually large. As yet Nyasaland has been free from the coffee disease, which, as in Brazil and India, does not appear to be able to penetrate far inland from the coast, though it has already committed ravages in German East Africa and in Natal.

EARLY BRITISH RACES.[1]

BEFORE proceeding to trace the early history of man in Britain, it is necessary to refer briefly to the physical changes which geologists tell us have occurred since the close of the Tertiary period in the configuration and temperature of the north-western portion of Europe.

At the beginning of the Pleistocene period, the temperature of Northern Europe became colder, and an ice-cap, like that which now covers Greenland, gradually extended itself probably as far south as Middlesex, and covered the greater part of Wales and the northern half of Ireland. This epoch is known as the Great Ice Age. At that time also the land was more elevated than now, so that Great Britain and Ireland formed part of the continent of Europe, and the western coast-line extended some three or four hundred miles further into the Atlantic Ocean than it does at present. This period of cold was succeeded by a more genial one, during which, but before the ice had disappeared, a great submergence of land and of the glaciers still upon it took place, varying at different parts of the country from 600 ft. to over 3000 ft. The climate again became colder, and on the higher parts of Wales, the North of England, and Scotland, glaciers were formed once more, but not to the same extent as formerly. Then followed, in late Pleistocene times,a re-elevation of the land to at least 600 feet above the present level, Great Britain and Ireland once more became joined to the continent, and the climate became temperate. In all probability the geographical conditions of Britain, or rather the British corner of Europe, in early and late Pleistocene times, were almost identical. Finally the land connection with the continent became severed by submergence, which went on till almost the present coast-line was reached; the sea once more rolled in over the beds of the German Ocean and the English Channel. These changes in the geographical conformation of the north-western part of Europe took place slowly, and were consequently spread over an immense interval of time.

According to some eminent geologists, man first took up his abode in the British portion of Europe, either during the early glacial or pre-glacial period. The evidence of his existence here at that early period rests upon the discovery of many flint implements of peculiar and special type on certain high chalk plateaus in Kent in drift resting on Pleiocene beds, in drift deposits of Norfolk and Suffolk, and in certain caves in which glacial drift is believed to be deposited over the flints. All these implements are of the rudest make, more or less stained, like the drift flints with which they are associated, of a deep brown colour. They show a considerable amount of wear, as though they had been rubbed and knocked about a good deal, so that the worked edges are commonly rounded off and blunt. In few instances have the implements been wrought out of larger flints, and the amount of trimming they have received is very slight, and has been generally made on the edges of rude natural flints picked up from old flint drift; indeed, sometimes she work is so slight as to be scarcely apparent; in other specimens it is sufficient to show design and object. These implements indicate the very infancy of art, and are probably the earliest efforts of man to fabricate tools and weapons from other substances than wood or bone. They give us some slight insight into the occupations and surroundings of the race who used them, as they appear to have been employed for breaking bones to extract the marrow, scraping skins, and rounding sticks and bones for use as tools or poles. From the absence of large massive implements, it would seem as though offensive and defensive weapons had not been much needed, either from the absence of large mammalia, or from the habits and character of these early people. Many archæologists are not satisfied with the evidence yet adduced as to the age of these flints, consequently of man's existence in Britain at this early date, and the question cannot be considered settled one way or other.

Whatever may be the ultimate decision as to the existence of pre-glacial man in Britain, all geologists and others are agreed that after the glacial period had passed away, and Britain had once more become a part of the continent of Europe after its submergence, a race of men known to us as Palæolithic man migrated into the country from the continent, across the valley of the English Channel, in late Pleistocene times. Man of this period is known to us from remains found in the river-drifts of

[1] A lecture delivered at the Royal Institution by Dr. J. G. Garson. We are indebted to Prof. Boyd Dawkins for permission to use the accompanying illustrations.

post-glacial age, and in the lower deposits of certain caves. As some evidence has been brought forward to show that the river-drift people, as they are called, are earlier than the cave-dwellers, we will consider the river-drift people first.

Remains of man from the river-drifts have only been found in the south of England from Chard, Axminster, and the Bristol Channel, in the west to the Straits of Dover, the lower Thames,

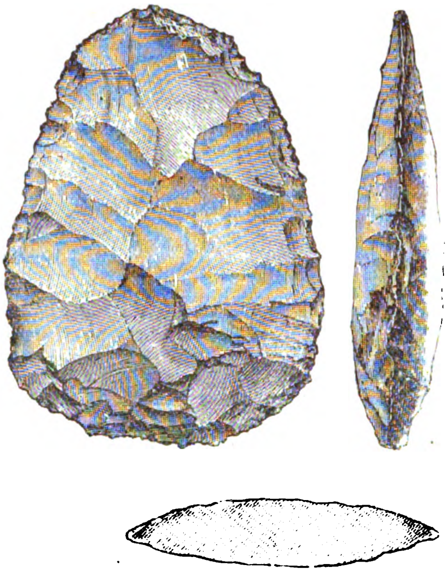

FIG. 1.

Suffolk, and Norfolk on the east, and as far north as Cambridge. They are conspicuous by their absence north-west of a line passing from Bristol to the Wash. The remains consist of a small portion of a skull, reputed to be of this period, implements of flint, quartzite, and chert, antlers of deer, and of certain fossil shells, probably used as ornaments.

The portion of skull was found by the late Mr. Henry Prigg,

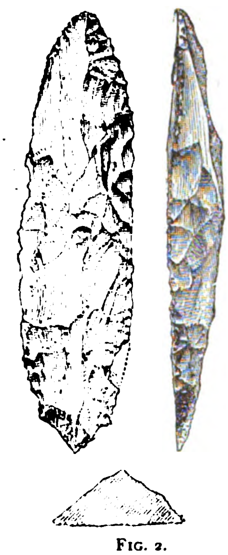

FIG. 2.

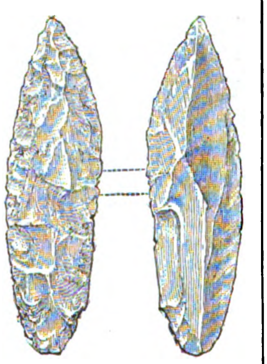

FIG.

in 1882, at Westley, in Suffolk, seven and a half feet from the surface, in a pocket of brick earth eroded in the chalk, and in an adjoining pocket two molar teeth of mammoth and four Palæolithic flint implements were found.[1] The fragment of skull was part of the vertex, and included the upper portions of the frontal and parietal bones, with part of the coronal and sagittal sutures. It was examined by Mr. Worthington Smith, and in transit to the finder of it was unfortunately smashed. As it was not a characteristic part of the skull, it shed little light on the cranial characters of its owner. With this exception, no human bones have been found in fluviatile deposits in Britain.

The implements from the river-drift consist principally of oval-pointed flints which have been fashioned by chipping, and were used without handles, oval or rounded flints with a cutting edge all round, scrapers for preparing skins, pointed flints used for boring, flakes struck off from blocks or cores by means of large hammer-stones, often of quartzite, and choppers of pebbles chipped to an edge on one side. The tools with which these implements were manufactured consisted of anvil stones of large blocks of flint, pointed flints or punches, and carefully

FIG. 4.

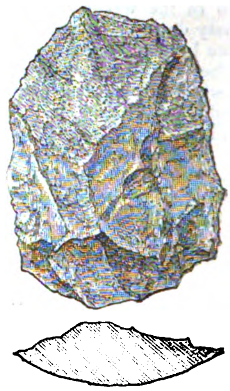

FIG. 5.

made fabricators. All the implements, though simple and rude, show signs of manufacture, the more finely finished specimens having been prepared by delicate chipping. Their manufacture seems to have been carried on at certain spots, on the banks of rivers and other places, where there was plenty of material to make them from. It will be observed that at this time there were no flint arrow-heads, and that man was but poorly equipped for the chase, although it was undoubtedly by that means he gained his livelihood. Besides these flints, man doubtless used wood and bone implements; indeed, pieces of pointed stakes of wood have been found on the Palæolithic floors where he worked, by Mr. Worthington Smith. Bead-like fossil shells

FIG 6.

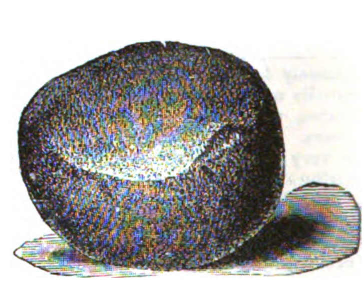

FIG. 7.

of *Coscinopora globulosa* have been found by Mr. Smith, with artificial enlargement of their natural orifices, which would indicate that they had been used for necklaces or amulets, so that primitive man seems not to have been without his personal adornments even at this time.

It is of importance to consider for a moment the animals which lived with man at this period. There are found in the same strata with him remains of the hippopotamus, two species of elephants and of rhinoceros, the cave bear and lion, the wild cat, hyæna, urus, bison, the wild horse and boar, stag, roe, reindeer, and other animals, many of which are now extinct. Man at that time had no domestic animals. The only clothing he had, if he wore any, was made from the skins of the animals he

[1] *Jour. Anthrop. Inst.*, vol. xiv. p. 51.

killed in the chase and used for food. Being far from the sea, if he used fish as food, they would be such as he was able to catch in the rivers.

Let us now trace man of this period on the continent. In the fluviatile deposits of the Somme and the Garonne, stone

FIG. 8.

implements have been found and recognised by such competent authorities as Sir John Evans, Mr. Franks, Prof. Boyd Dawkins, and others, as identical with the drift Palæolithic implements found in England. Similar ones have been

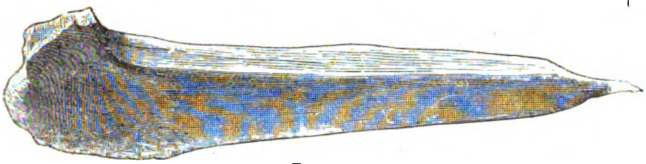

FIG. 9.

found in Spain, near Madrid, in Italy, Greece, Germany, and other places in Europe; also in Northern Africa, Palestine, and India. From these finds we learn that man has lived in a similar state of civilisation to what he did in Britain,

FIG. 10

over a very wide area; they also show that he must have existed in this stage of culture for a very long time.

As regards his skeletal remains on the continent, a few have been found. At Canstadt, near Stuttgart, it has been stated that

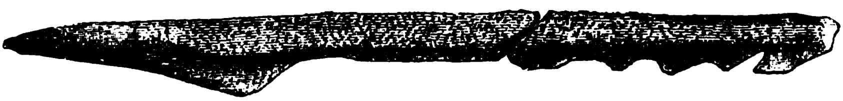

FIG. 11.

portion of a skull was discovered, in 1700, in loess deposits, with bones of the cave bear, hyæna, and mammoth. At Eguisheim, near Colmar, Schaffhausen, portion of another cranium was found with mammoth and other animal remains of this period. At

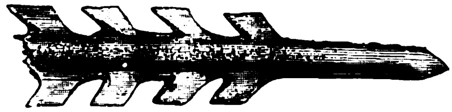

FIG 12.

Clichy, in the valley of the Seine, a skull and some bones were found at depths varying from 4 to 5·4 metres from the surface in undisturbed strata, with mammoth, woolly rhinoceros, horse, and stag. The skull in these instances is long and narrow in

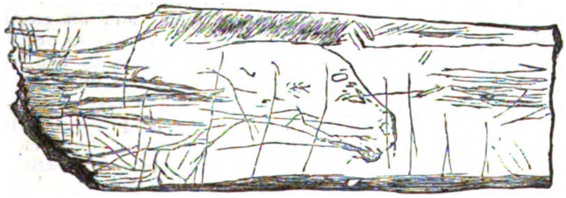

FIG. 13.

shape, with very prominent supraorbital ridges and glabella; the thigh and leg bones of the Clichy skeleton are laterally compressed, the former having a greatly developed *linea aspera*, the latter being markedly platycnemic. Further reference will be made to these specimens when we deal with the cave skeletons.

Caverns and rock shelters are well known to have been used not only by man, but also by animals, from remote times down to the present day. The strata which have been deposited in them at different times by their successive occupants, and the vicissitudes

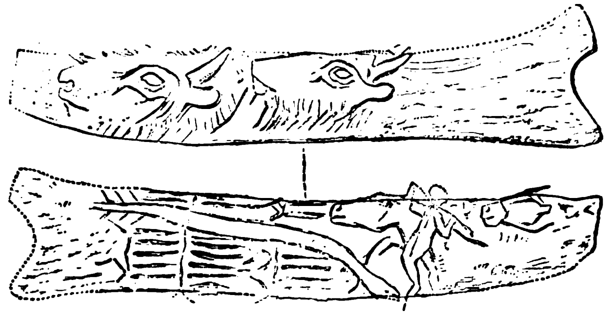

FIG. 14.

of climate, are often well marked, and give much valuable and reliable information, but great care is required in discriminating the different periods which their contents represent. The remains of Palæolithic man deposited in caves are much more widely distributed over England than those from the river-drifts, having been found as far north as Yorkshire and Derbyshire, in North and South Wales, Gloucestershire, Monmouthshire, Somersetshire, and Devonshire, also in Ireland, although these latter have not been much worked. The Palæolithic cave strata shows three sub-strata; in the two lower ones the flint implements are precisely similar to those of the river-drifts, but flat pebble implements of quartzite are also found with part of the

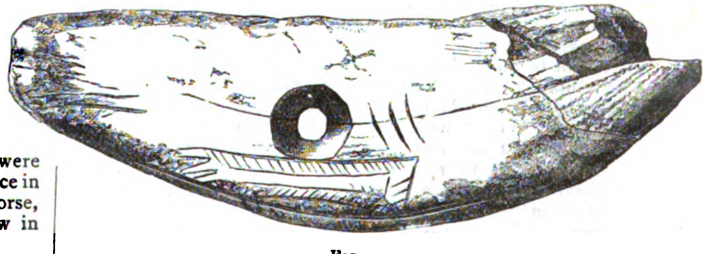

FIG. 15.

natural smooth surface retained, while the rest is chipped and fashioned into an implement.

In the upper substratum more highly finished articles, which would point to a higher and probably a different social condition, later in time, are obtained. We have in this higher substratum flints of oval and lanceolate form, trimmed flakes, borers, and rounded hammer-stones (Figs. 1, 2, 3, 4, 5, 6, and 7). These are of smaller size than the earlier implements, and some of them had evidently been let into handles of wood. Bone needles, with an eye bored at one end (Fig. 8), bone awls (Fig. 9), scoops (Fig. 10), and harpoons (Figs. 11 and 12), barbed on one or both sides of deer's antler, are also met with. Of great importance are the representations of animals which have been found incised on bone, as, for example, the portion of rib with the incised figure of a horse upon it, found in this layer in Robin Hood Cave in Derbyshire (Fig. 13).

No portions of the human skeleton have been found in the Palæolithic stratum of British caves, except a single tooth.

On the continent many caves have been discovered in France, Belgium, Germany, and Switzerland, with similar deposits and implements to those found in England, and showing also the same two stages of culture. More numerous examples of figure carving of the same type as that found in the Derbyshire cave have been obtained in French caves (Fig. 14), and the teeth of carnivorous animals and shells, both artificially bored for ornaments (Fig. 15).

By associating British and continental evidence we can form a good idea of the mode of life of the cave-dwellers of Palæolithic times. The caves gave him shelter in cold weather, from which he further protected himself by fires, and clothing made from the skins of animals he secured in the chase, sewn together by means of bone needles and tendons of reindeer for thread. Armed with flint-tipped spears and daggers of bone ornamented with carved handles representing the chase, he lived by hunting the reindeer, the wild horse, and the bison; he also lived on birds and fish, which he speared with barbed harpoons. The game he brought home was cut up with flint knives, and cooked; the long bones were broken with heavy flints for the marrow they contained, which was evidently considered a delicacy. When not engaged in the chase, the manufacture of flint implements must have formed an important part of his home work. He must also have spent much time in carving ornaments on bone. These, it may be remarked, show that he was an artist of no mean order in depicting animals, but give us little information regarding his own form, as he seldom represented himself, and when he did he figured himself in miniatures and naked (Fig. 14); they also show that he was in the habit of wearing long gloves to cover his hands and arms (Fig. 15). Besides ornamenting himself with perforated shells, pieces of bone, ivory, and teeth, he probably painted his body of a red colour. He, like the river-drift people, possessed no domestic animals, and had no dog to assist him in hunting.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Dr. J. Lorrain-Smith has been appointed Demonstrator in Pathology, in the place of Mr. L. Cobbett, who has been elected to the John Lucas Walker Research Studentship.

An Isaac Newton Studentship in Astronomy, worth £200 a year for three years, will be vacant in the Lent Term. Candidates must be B.A.'s under the age of 25 on January 1, 1895. Names and testimonials are to be sent to the Vice Chancellor by January 31, 1895, with a statement of the course of study or research proposed.

At the biennial election to the Council of the Senate, held on November 7, Dr. Peile, Mr. C. Smith, Dr. Maitland, Dr. Sidgwick, Dr. D. Macalister, Dr. Forsyth, Mr. Whitting, and Mr. R. T. Wright were returned for a period of four years.

Dr. Donald Macalister was, on November 9, elected without opposition to represent the University on the General Medical Council for a second term of five years.

This year has been memorable as the twenty-first anniversary of the establishment of the University Extension Lectures, the system having been founded by the University of Cambridge in the year 1873. The twenty-first annual report of the Cambridge Syndicate has just appeared. During the past session seventy-five science courses have been delivered at various centres. This number is less than those of the last two or three years, the diminution being attributed almost entirely to the decrease in the temporary work undertaken by the Syndicate during the preceding sessions for the technical instruction committees of various County Councils. Whereas in some places grants of money from the local authorities have enabled local committees to arrange more easily courses of University Local Lectures on scientific subjects, in others the cheap technical classes organised independently by the local authorities have influenced very injuriously the attendance at the local lectures, and in some cases caused their discontinuance. The County Councils are just beginning to feel their feet, but it seems ungenerous of them to forget that they were helped over their initial difficulties by University Extension Lectures. The Technical and University Extension College at Exeter, which is under the joint management of the local authorities and the Cambridge Syndicate, has now completed its first session's work, and about six hundred regular students have already joined the College. Its success affords a striking illustration of the method by which under the Local Lectures system permanent educational institutions can be established. It should not be forgotten that the Cambridge University Extension movement was similarly largely instrumental in the foundation, a few years ago, of University College, Nottingham, Firth College, Sheffield, and other local colleges.

THE *London Technical Education Gazette*, the first number of which has just been published, is intended to contain the official announcements of the Technical Education Board of the London County Council; notices of important steps in technical education taken by the various institutions in London; and useful information bearing upon the work. In the list of the conditions which have to be fulfilled by evening classes in science, in order to obtain grants from the Board, we are glad to note the following:—"That as a condition of aid being granted by the Board for the teaching of chemistry, metallurgy, physics, mechanics, and botany, it will be regarded as indispensable that provision should be made, to the satisfaction of the Board, not only for the experimental illustration of the lectures or class teaching, but for experimental work by the students themselves, either in laboratories belonging to the institution, or, where this cannot be arranged, in the laboratories of some neighbouring institution with which the class should be associated; and every lecture must be followed by at least one hour's practical work on the same evening, or some other evening in the same week."

SCIENTIFIC SERIALS

Wiedemann's Annalen der Physik und Chemie, No. 11.—Experimental researches on the origin of frictional electricity, by C. Christiansen. Friction by itself does not generate electricity. The appearance of the latter is due to chemical decompositions which are initiated by contact and completed on separation. These results are those of experiments with a tube coated on the inside with various insulators, arranged so that mercury could be brought into contact with them and withdrawn, after which a charge was indicated by a galvanometer.—On thermo-couples of metals and saline solutions, by August Hagenbach. In the case of couples consisting of metals and their salts, the E.M.F. increases with the dilution, and more rapidly than the difference of temperature. In combinations of platinum with hot and cold saline solutions the same acids give about the same forces, and differences of concentration have a very marked influence. The highest E.M.F. obtained was that of a platinum-cupric-chloride couple, which, with a 5·6 per cent. solution, and with the two communicating portions of the liquid at 25° and 80° respectively, gave an E.M.F. of 0·1541 volts.—Changes of length produced by magnetisation in iron, nickel, and cobalt ellipsoids, by H. Nagaoka. The optical lever method was employed. As the field intensity increases, iron first expands and then contracts, going through the opposite stages on reversing, and showing a decided hysteresis. Nickel simply contracts. Cobalt contracts first and then expands, the expansion increasing to a limiting value as the field intensity increases.—On elliptically-polarised rays of electric force, and on electric resonance, by L. Zehnder. The author shows how to produce circularly and elliptically polarised electric rays by two wire gratings placed one behind the other, with the directions of wires crossed.—On refraction and dispersion of rays of electric force, by A. Garbasso and E. Aschkinass. To produce a prism capable of affecting ether waves of the length of those due to Hertzian oscillations, a prism was constructed of a series of parallel glass plates, upon which were stuck "resonators" made of strips of tinfoil. This was placed between an exciter and a suitable resonator. It was found that the rays were refracted by angles differing according to the wave-length. The deviations for three different resonators were 9° 6′, 7° 18′, and 5° 24′ respectively.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, October 26.—Prof. A. W. Rücker, F.R.S., President, in the chair.—The meeting was held in the rooms of the Chemical Society, Burlington House.—In opening the proceedings the President said the occasion might be regarded as another sign that the boundary between Chemistry and Physics was breaking down. On behalf of the Council he tendered the thanks of the Physical Society to the Chemical Society for the use of the rooms.—Prof. H. E. Armstrong, President of the Chemical Society, said his Council offered a cordial welcome to the Physical Society. The change, he thought would prove of much greater importance than a mere removal. Now that the childhood of the Physical Society was passed, its manhood involved new responsibilities, and great opportunities for good presented themselves. The Physical Society of London ought now to become the head-centre of physics in the United Kingdom. He (Dr. Armstrong) was pleased to learn that the Society had undertaken the preparation and publication of abstracts of physical papers appearing in foreign periodicals, and said the matter was of such great importance that it should be done thoroughly. In a work of such a magnitude, he regarded the co-operation of other societies, such as the Institution of Electrical Engineers, as absolutely necessary.—The President, in acknowledging the welcome, said the Physical Society was extremely obliged to the President and Council of the Chemical Society for the great benefits conferred. Dr. Armstrong's advice to go ahead would not be forgotten. He then announced that at future meetings tea would be provided for members at 4.30.—The exhibition of a voltameter by Mr. Naber was postponed.—Mr. E. H. Griffiths read a paper on the influence of temperature on the specific heat of aniline. After pointing out that most observations of specific heat depend on water, whose capacity for heat varies considerably with temperature, the author said large differences existed between the values obtained by different observers as the latent heats of evaporation of water and other liquids, and these differences were probably due to the variability of the water standard, which had been erroneously assumed constant. Precise measurements in calorimetry were of such great importance that the exact relation between the capacity for heat of water and its temperature should be completely determined. With apparatus such as he had used with aniline, this could be done in six months, provided someone could be found who could devote his whole time to the subject. The results of his own experiments were expressed in terms of the capacity for heat of water at 15° C. (at which $J = 4 \cdot 198 \times 10^7$ ergs.), and hence were referred to a definite standard. A great desideratum in calorimetric work was a calorimeter whose surroundings could be kept at a very constant temperature. This he had obtained by using a tank holding about 20 gallons of water, in which a steel vessel, shaped like a hat-box with hollow sides and bottom, was immersed. The cavity was filled with about 70 pounds of mercury, and served as the bulb of a thermometer; a tube communicating with this bulb acted as a regulator to control the gas supply which heated the water in the tank. The tank water was circulated rapidly by a screw-propeller. Under ordinary conditions the temperature of the outside of the steel chamber could be kept constant within 1/100° C. The calorimeter itself was of brass, and suspended by glass tubes from the lid of the steel chamber. A stirrer worked by an electromotor kept the contents in rapid motion. In the experiments on aniline, heat was supplied to the liquid in the interior by maintaining known potential differences (equal to some multiple of the E.M.F. of a Clark's cell) between the ends of a coil of German silver wire placed inside. The rate of rise of temperature of the inside over the outside was measured by platinum thermometers, one of which was placed in the calorimeter, and the other embedded in the walls of the steel vessel surrounding the calorimeter. By this means differences in temperature of 1/1000 of 1° C. could be detected with certainty. A special method of adjusting the potential difference between the ends of the German silver wire was employed, by which the constancy could be maintained within 1 part in 10,000. To minimise corrections arising from heat generated by stirring the liquid, and that lost by radiation, &c., from the calorimeter, the experiments were made about temperatures at which these corrections balanced each other; the rise of temperature was then due to the electric supply alone. The specific heat, S_1 of the liquid at temperature θ_1 could then be determined from the formula

$$\frac{d\theta_1}{dt} = \frac{E^2}{JR_1(S_1M + w_1)}$$

where $\frac{d\theta_1}{dt}$ = rate of rise of temperature at temperature θ_1

J = mechanical equivalent of heat,
E = potential difference between the ends of the coil,
R_1 = resistance of the coil,
M = mass of liquid,
and w_1 = water equivalent of calorimeter at temperature θ_1.

Experiments were made with different values of E, and two widely different masses of liquid were used. The author was thus enabled to find S_1 without knowing w_1. Having found S_1, the water equivalent of the calorimeter could then be determined. Many important details of construction and manipulation of the apparatus, as well as the method employed in reducing the results, are given in the paper. The final values for S_1 and w_1 at several temperatures are given below.

Temperature.	Specific heat of aniline.	Water equivalent of calorimeter.
15° C.	0·5137	79·82
20	0·5155	80·11
30	0·5198	80·90
40	0·5244	82·19
50	0·5294	83·39

The aniline employed was supplied by Messrs. Harrington Bros. as "pure colourless," but had initially a light brown tinge. After being in use some time, the colour had darkened considerably, but its specific heat had not sensibly changed. Recently he had tried a hydrocarbon liquid which promised to be still more satisfactory as a standard liquid in calorimetry. In the course of his remarks the author said a name for "capacity of heat per unit volume" was greatly needed, and invited suggestions. Dr. Armstrong thought the author had made a particularly happy selection in aniline, for it could now be obtained in any quantity absolutely pure. When pure it did not discolour on exposure, and would probably be very satisfactory as a standard liquid. He doubted whether any hydrocarbon could be better. Prof. Ayrton congratulated the author on the extreme accuracy obtained. Recently he had arranged an experiment for determining the mechanical equivalent of heat by the electrical method, which gave very accurate results without any corrections whatever being necessary. Prof. S. P. Thompson thought the whole phraseology of specific heat required revising. Prof. Perry agreed with Mr. Griffiths that a name for "capacity for heat per unit volume" was greatly needed, and Mr. Lucas suggested "heat density," but this was not satisfactory. Dr. Sumpner said most text-books on physics attributed the advantage of the mercury thermometer to the low specific heat of mercury, whereas the capacity for heat per unit volume was the important factor. Mr. Watson inquired to what temperature the alloy which the author had used to connect glass to metal had been tested? The President said the paper was of great importance because it dwelt with the application of electrical methods to thermometry. The mercury thermometer had been quite superseded for work such as had just been described. Mr. Griffiths, in reply to Mr. Watson, said the alloy had been used successfully between 10° and 62° C. It gave way at 71° C. He was glad to learn from Dr. Armstrong that aniline could now be got pure. Prof. Ramsay had written to say he did not think the slight impurities in ordinary aniline would have much effect on its specific heat. Mr. Blakesley asked if aniline could be taken as pure if it did not change colour on exposure. Dr. Armstrong, in reply, said yes, if the boiling point was also constant.

PARIS.

Academy of Sciences, November 5.—M. Lœwy in the chair.—On an apparatus serving to demonstrate certain consequences of the theorem of areas, by M. Marcel Deprez. This is an apparatus designed to show that a body passing freely through space may rotate on its own axis without suffering the application of any exterior force, such rotation being produced by interior movements of parts of its system.—On the theorem of areas, by M. P. Appell.—On the theory of flow for a weir with depressed or partly submerged liquid sheet, in the case where a horizontal *armature* gives the inferior maximum contraction, by M. J. Boussinesq.—On the vaporisation of carbon, by M. Henri Moissan. The heat of the electric furnace enables carbon to be volatilised; the sublimed carbon is always deposited under the form of graphite at ordinary pressures, and there is no evidence whatever of the liquefaction of the carbon, for instance the lid of a carbon crucible did not adhere when the whole mass had been converted into graphite, and a carbon needle heated in a carbon tube did not in any case become attached to the latter. Previous experiments have, however, shown that under great pressures carbon may be fused, and diamond is then formed.—New observations on the menhirs of the Meudon woods, by M. Berthelot.—Note by M. Maurice Lévy accompanying the presentation of his "Study of the mechanical and electrical methods of traction of boats." The author gives a short account of the contents of the first volume of his work dealing with cable traction only.—M. Bouquet de la Grye, in the name of the Bureau des Longitudes, presented the "Connaissance des Temps" for the year 1897. This volume contains, on the maps of solar eclipses, the curves passing through the points on the earth at which the commencement and end of the eclipse are simultaneous. The ecliptic elements of the great planets and their satellites, including their elongations and the elements of Saturn's ring, are also given.—Observations of the new planet BE, made at Paris Observatory, by M. G. Bigourdan.—The polar snows of Mars, by M. C. Flammarion (see "Our Astronomical Column").—Relations between the vapour pressures of a body in the solid and in the liquid state: influence of pressure on the temperature of fusion, by M. A. Ponsot.—Influence of form on the sensitiveness to light and aberration of the eye, by M. Charles Henry.—Researches on mercuric nitrates, by M. Raoul Varet. The heats of formation are determined. In the dissociation of mercuric nitrate by water the least endothermic of the possible reactions is the one that takes place. Nitric acid, like sulphuric, picric, acetic, and oxalic acids, is displaced completely from mercuric combinations by hydrochloric and by hydrocyanic acids.—On the campholenic acids and the campholenamides, by M. A. Béhal.—On the presence of methyl salicylate in some native plants, by M. Em. Bourquelot.—On the formation of new colonies by *Termes lucifugus*, by M. J. Pérez.—The defence of the organism against parasites among insects, by M. L. Cuénot.—External characteristics of chytridiosis of the vine, by M. A. Prunet.—On a mycobacterial disease of *Tricholoma terreum*, by M. Paul Vuillemin.—Defence of "Saharien" as a name for the last geological period, by M. Mayer-Eymar.—On the presence and distribution of glycogen in tumours, by M. A. Brault.

BERLIN.

Meteorological Society, October 9.—Prof. Hellmann, President, in the chair.—After the President had dwelt on the loss sustained by meteorology owing to the death of von Helmholtz, Dr. Schwalbe spoke of his own endeavours to utilise for scientific purposes the curves of temperature obtained from the "Uranus" pillars. He found among the many meteorological pillars in Berlin which had given continuous records during the years 1892 and 1893, very few whose readings corresponded with those of control instruments. Taking the month of July for each year, he had endeavoured to arrive at the mean daily temperature by taking the mean of the temperatures registered every hour of each day in the month. He found this mean temperature to lie between the values of the expressions $\frac{6+2+10}{3}$ and $\frac{7+2+9+9}{4}$.—Dr. Kassner had instituted observations during the year on cloud-waves, to which, since Helmholtz' researches on the formation of waves when two layers of air of different density and travelling with different velocity move past each other, meteorologists have devoted very special attention. From these it appears that the above form of cloud, consisting mostly of cirrus and cirrocumulus, usually causes deposits. The speaker expressed the wish that thorough and continuous observation of this phenomenon might be made in order to test it.

PSYCHOLOGY OF MENTAL ARITHMETICIANS AND BLINDFOLD CHESS-PLAYERS.

Psychologie des Grands Calculateurs et Joueurs d'Échecs. Par Alfred Binet. (Paris: Hachette and Cie., 1894.)

WHOEVER may hereafter write about mental imagery will be imperfectly equipped for his task unless he has mastered the contents of this curious and instructive volume. It analyses the mental processes of two groups of remarkable men—those who possess extraordinary powers of mental arithmetic, and those who are capable of playing eight or more games of chess, blindfold and simultaneously. The idea of making the inquiry is due to the late Prof. Charcot; its prosecution has been conducted almost wholly by M. Binet, and principally at his laboratory in the Sorbonne. The prosecution of such an inquiry with the accuracy needed by modern psychology is exceedingly difficult, and it is also very difficult to express such results as may be obtained from it, in unambiguous language. The author has, however, succeeded in the latter as well as in the former, and he has framed many happy turns of expression which will contribute to the much desired evolution of psychological language.

The book begins by quoting the series of historical cases of mental arithmeticians, that was published by Scripture in 1881, in the *American Journal of Psychology.* They suffice for making useful generalisations, though few of the cases were tested with much precision. Then the original work commences. It refers to two remarkable calculators, who are now living, both of about the age of twenty-six, but whose mental processes entirely differ in their most obvious characteristics. The one is Inaudi, a Piedmontese, who performs his mental sums wholly, or almost wholly, by imagined sounds, *one*, *two*, *three*, &c.; the other is Diamandi, a Greek, who attains the same end almost wholly by imagined figures, as 1, 2, 3, &c. The careful testing of these two men, and the analyses and comparisons of the results, show the strange unlikeness of human minds in the above well-marked features, accompanied, it may be, with a nearer likeness in those deeper and more obscure qualities, which are exceedingly difficult to grasp. I, myself, had the pleasure of testing Inaudi at my own house, in company with a few scientific friends. Even the small number of experiments that there was then time to make, rendered it clear to my own mind that the conclusions which had been arrived at, after prolonged and careful experiments in France, were quite justified, namely, that he performs his long sums almost wholly by his auditive imagination, supplemented possibly by the motive, or gesture sense, but that the visual form of imagination was practically absent during the calculations. His case is an extremely rare one, and proportionately valuable for study. On the other hand, Diamandi is an excellent example of the common type of mental calculators, who work almost wholly by the visual imagination. A comparison between the achievements of Inaudi and Diamandi under similar tests, is the main feature of the first half of Binet's volume. He succeeds in distinctly negativing the assertion that the visual memory, even of a man who is so exceptionally gifted in that way as Diamandi, resembles actual vision either in its accuracy or in its completeness. Thus if a small square table of twenty-five figures, five figures in breadth and five in height, is shown to and learnt by Diamandi, he takes only nine seconds to repeat them in successive lines, but if he is asked to repeat them in the order of the columns, he is just four times as long in doing so, whether the columns are mentally read from their tops downwards, or from their bottoms upwards. He does not therefore read the figures as if they were written on a mental blackboard, which could be done as easily in any one direction as in any other, but he has, in some obscure way, to puzzle the figures out. When another table of twenty-five figures is taken, in which the figures are variously coloured, Diamandi's power of re-presenting colours being about as strong as that of re-presenting form, he has no difficulty in learning them, but he does it by two successive operations, first learning the figures and then the colours, and he is consequently twice as long over his task. This could hardly be the case if the visualised schedule had the completeness of an "after-image" or of a photographic plate.

A great difficulty in the way of testing the power of the memory of professional calculators is caused by their habit of accumulating large stores of mnemonic helps, which produce results that simulate those of a direct memory. It is indeed difficult for any one to free himself wholly from the use of such helps, which arise unbidden, more or less consciously, certain runs of figures, or accidents of position in the page, being more readily fixed in the memory than others. Binet's chapter on this subject is very instructive.

The most famous calculating boys had their calculating faculties developed very early in life. Many began to calculate of their own accord before they could read or write, and for the most part they were born in humble circumstances. It is found, so far as present information goes, that they did not inherit their gifts, except in a few cases, of which the Bidder family is a conspicuous instance. For my own part, I hesitate for awhile to accept the above negative result as a fact, and on the following grounds. Two mental peculiarities have to concur in the making of a calculating boy; the one is a special capacity for mental calculation, and the other is a passion to exercise it. Both of these peculiarities are rare, and they are not necessarily coordinated, therefore the chance of their concurrence in full force may be very small indeed. I have, however, reason to suppose that the capacity for mental calculation is more common than is usually believed, but that it does not commonly interest its possessor, and may even be unknown and consequently neglected by him. Trustworthy evidence for or against its hereditary transmission could hardly be obtained under these conditions. I may quote the case of a deceased lady of remarkable ability, which I indirectly verified to my own satisfaction at the time. She told me, and her husband confirms my recollection, that one night, while travelling to the south of France, she could not sleep, so she amused herself, as is common on such occasions, with various idle trains of thought. Then it occurred to her to try mental sums, and finding, much to her surprise, that she had great facility in doing them, she became interested and exerted herself to the utmost. Before her train had reached Lyons, she had successfully multiplied one series of eleven figures into another series also of eleven figures. She subsequently trained herself to multiply fifteen figures into another fifteen. I am informed that her first attempt at the latter had one error, and, on being told that it was not correct, she went over it again mentally and gave the correct result. Another case comes to my memory. It appears that there was a craze for mental arithmetic in the period 1820-30, or thereabouts. My father was interested in the subject and made experiments on many friends and on all his servants, with the result, as I used to hear, that the best performer of all, and a really remarkable one, was a somewhat obtuse and uninteresting servant girl. She took no especial pleasure in calculation, and on that account would never have made a study of its processes by herself; nevertheless, she had the capacity for using them. An innate passion for arithmetic, such as all the great calculators possessed, is certainly uncommon. If only a moderate passion for it should exist, it is likely to become repressed by circumstances, because it is nearly useless to the possessor. It is difficult to imagine that anyone who was not fascinated by figures would devote the best part of his time and energy to them. Professional calculators are said to be usually (by no means always) narrow-minded, and to have their heads filled with mnemonic contrivances.

I may be permitted to allude to an inquiry analogous to that which has here been made into the visual and auditive imaginations, which I made on myself, on a small scale, in respect to the olfactile imagination. I tried to perform mental arithmetic, not by imaginary visual symbols, or by imaginary sounds, but by imaginary smells. As sums are set in the two former cases, either in really visible symbols or in really audible sounds, while the results are reached through imaginary ones, so in my experiment the sums were set in real odours, and were worked out through imaginary odours. I described the result briefly, not many months ago, in the *American Psychological Review*, and think the inquiry worth repetition, especially by experimenters who may possess the power of re-presenting odours to themselves more vividly than I have. It would enable them to perceive the processes gone through in mental arithmetic from a new point of view. My apparatus consisted of glass tubes, each drawn to a nozzle at one end like a short syringe. One end of a piece of india-rubber tube, six or eight inches long, was pushed tightly over the other end of the glass. A different odorous substance, camphor, carbolic acid, gasolin, &c., was inserted and packed lightly with cotton wool in the several tubes, whose ends were afterwards tied up. On grasping one of these tubes tightly, at the moment when its nozzle was brought to the nostril, a whiff of its peculiar odour was ejected and simultaneously sniffed up. This could be rapidly repeated three or four times without much diminution of the odour of the whiff. (An arrangement with valves would have much improved its action, by ensuring that no air should be ejected that had not passed through the scent.) I thus possessed a set of tubes that could be used *smellingly*, in the same way as the symbols 1, 2, 3, &c., are used visually, or the words *one*, *two*, *three*, &c., are used audibly. This is not the place to enter into further details. I only desire to emphasise one fact which the experiment taught me, namely, the existence of a large substratum of mental work that my power of introspection failed to penetrate. I progressed far enough to be able to add or subtract small sums, so that a 1 followed by a 2, both in smell language, associated themselves at once with the imaginary sniff of a 3, whenever I was engaged in addition, or with that of a 1 when I was engaged in subtraction. But the two associations of 3 and 1 never clashed; they were mutually exclusive. I could not ascertain through introspection what was the nature of the *attitude of mind* which determined whether the association was to be the one needed for addition or for subtraction, for division or for multiplication. Another point that strongly impressed me was the enormous amount of labour that must have been gone through by all of us in thoroughly learning the multiplication table. I made a very few similar experiments with the gustatile or taste-imagination, but they were troublesome, and I did not follow them up.

There is little room now left to speak of the latter half of Binet's volume, which refers to the great chess-players, who play eight or more games blindfold and simultaneously. The evidence is overwhelming that the faculty of visualising is not exercised by them in the same sharp and distinct way that it is commonly supposed to be They do *not* see the chessmen and the complete board all at once and with clear definition, but they commonly see all besides the portion they are considering, more or less vaguely, and they appreciate the positions of the men as hidden centres of forces. Two letters, which close the volume, by the distinguished chess-players Goetz and Tarrasch, seem to me models of exact introspection and of clear description.

FRANCIS GALTON.

THE COLLECTED WORKS OF OLBERS.

Wilhelm Olbers, sein Leben und seine Werke. Im Auftrage der Nachkommen herausgegeben von Dr. C. Schilling. Erster Band, Gesammelte Werke. xix. + 707 pp. 8vo., with portrait. (Berlin, 1894.)

GERMANY has not produced as many amateur astronomers as England has, but among them the man whose complete writings have now been published occupies a most remarkable place. Olbers was an amateur, but his work was that of a professional astronomer. Though occupied all day in the extensive practice of a physician, he devoted his nights to searching for comets, making micrometric observations of these bodies, whether found by himself or others, with the annular micrometer, an instrument the immense value of which he was the first to perceive, and computing their orbits by the simple method devised by him, which he is said first to have applied practically while watching at the bedside of a patient. At the top of his house in the Sandstrasse in Bremen he had his exceedingly modest observatory, at the equipment of which, consisting only of small and portable instruments, any modern amateur would turn up his nose. For years he was obliged to correct his clock by tedious observations of equal altitudes with a sextant and artificial horizon, until he devised the simpler and quicker method of watching the disappearance of stars behind a distant tower. But his labours brought him a plentiful reward, not only in the discovery of the planets Pallas and Vesta and various comets, and in the renown which these and his important publications procured him, but also in the friendship of Schröter, Zach, Gauss, Bessel, Schumacher, Encke and others, who always in their letters and published writings mention him with the greatest veneration.

The publications of Olbers are scattered through many volumes of the various periodicals of his time, some of which are not readily accessible now-a-days. But most of them are still of the highest importance, not only those describing the method which is practically the only one used for computing cometary orbits, but also those in which Olbers has deposited the results of his deep study of the literature of comets, ancient and modern, as well as the many articles which bear witness to his having possessed mathematical abilities of no mean order. The appearance of the complete edition of his works now before us will therefore be hailed with pleasure by astronomers. It is to be followed by two other volumes, containing the correspondence of Olbers with Gauss, and a biography by the editor.

The celebrated and epoch-making memoir on the most convenient method of computing the orbit of a comet was printed separately (in 1797), and it naturally opens the volume now published. After it (and the appendix published in the *Jahrbuch* for 1833) the editor has placed twelve other papers under the common heading "Abhandlungen." It is not easy to see why these particular papers have been distinguished in this manner. It is not because they are the longest, for some of them occupy only a few pages, so it must be because the editor considers them specially important. But if so, why are others, fully as important, not put along with them, as, for instance, the classical paper on the tail of the great comet of 1811? The arrangement of the other papers in six groups also frequently challenges criticism. Under the heading "Comets" are given no less than 110 papers, but half a dozen notes on comets are relegated to the group of "Miscellanea from letters," near the end of the book, apparently simply because they were written in the form of letters to the editors of various journals. The useful index at the end of the volume will, however, enable the reader to read these notes in connection with the other papers on comets. On the other hand, the papers on the comets of 1802 and 1811 (pp. 293 and 315) are made up of pieces detached from two editorial articles in the *Monatliche Correspondenz*, omitting all the observations not made by Olbers; and this patchwork might, perhaps, better have been put among the miscellaneous notes. It would have been much simpler, and apparently more satisfactory, if all the papers (except the separately published book of 1797) had been printed in chronological order, as the index would even then have made it easy to pick out papers on any special matter. It is, however, more to be regretted that the editor has not seen fit to add some explanatory notes, which would greatly have increased the value of the book to young students of astronomy, who cannot be supposed to be thoroughly acquainted with its literature. We shall only point out a few cases where such notes would have been particularly useful. The first is Olbers' letter to Encke about the mysterious comet alleged to have been observed by D'Angos at Malta in 1784, reprinted here from Encke's well known paper with the startling title, "Imposture astronomique grossière du Chevalier D'Angos." We certainly think that the editor might in a short note have given references to the more recent investigations on this matter by d'Arrest and Gyldén, which render it at least very possible that D'Angos really found and on two nights observed a comet. At any rate we cannot be certain that the whole matter was nothing but a fraud, and a different heading to the article might have been chosen. On page 226 it should have been pointed out that the orbit of the comet of 1558 has also been computed by Hoek (from observations by Paul Fabricius), whose results differ considerably from those of Olbers. On p. 228, Olbers suggests that the manuscripts of Father Schall in the Vatican might contain comet observations from 1618. It would have been useful to have added a note to the effect that these manuscripts have afterwards been found not to contain any such observations (*Corresp. Astron.* v. p. 143). Similarly the article on Cacciatore's supposed planet of 1835 (p. 526) should have been accompanied by a note referring the reader to the calculations of Valz and Luther, as well as to NATURE, vol. xviii. p. 260, which might prevent some rash student from wasting his time on this object.

The papers have been reprinted from the originals without any alterations, so that even errors pointed out in subsequent papers have been allowed to stand (*e.g.* pp. 523 and 538, compare pp. 649 and 542). Some papers will be quite new to most readers, as they were published in journals of limited circulation, such as Harding's *Kleine Ephemeriden*, *Göttingische Anzeigen*, and Gruithuisen's *Analekten* and his *Jahrbuch*. The charming character of Olbers is seen in his notes to Gruithuisen, in which he frequently gently corrects mistakes in the writings of this enthusiastic but somewhat erratic observer. In an appendix are given two papers of 1787 and 1788 on mesmerism. Olbers' dissertation for the degree of M.D. (De oculi mutationibus internis, Göttingen 1780) is not reprinted.

The book is well printed, and has as frontispiece an excellent portrait of Olbers. In addition to a table of contents and an index, it contains a list of all the papers, arranged according to the journals in which they first appeared. No mention is here made of the catalogue of cometary orbits (published in Schumacher's *Abhandlungen*); but this has not been reprinted, and is of course long ago superseded.

In laying aside this splendid volume, we cannot refrain from making one more remark. We have now the collected works of Laplace, Gauss, Bessel, Encke, Olbers; how long are we to wait for a complete edition of the works of William Herschel?

J. L. E. D.

QUATERNIONS.

Anwendung der Quaternionen auf die Geometrie. Von Dr. P. Molenbroek. (Leyden: E. J. Brill, 1893.)

The Outlines of Quaternions. By Lieut.-Colonel H. W. L. Hime. (London: Longmans, Green, and Co., 1894.)

IN these books we have evidence of the growing demand for quaternion literature. Dr. Molenbroek's work is the promised sequel to his first volume on the Theory of Quaternions, and contains many admirable examples of the application of the method to geometry. All who are familiar with Hamilton's and Tait's classics on the subject will recognise many of these examples as old friends, taken almost verbatim from their original sources. In not a few of the applications, however, Dr. Molenbroek ventures into fresh fields, and shows that he can use quaternions with ease and power. It is interesting to notice the occasional effective use of the conjugate quaternion, an invention of the great master which is apt to be lost sight of after the foundations of the calculus have been laid. The treatment throughout is on the familiar Hamiltonian lines, the author's aim being development and not fancied improvements. The book consists of six chapters, in which are taken up—to name a few of the most important applications—spherical trigonometry, the plane and sphere, quadric surfaces, surfaces in general, curves in space, and the theory of rectilinear rays. The elementary properties of the remarkable operator ∇, and the integration of partial differential equations of the first and second orders, are discussed as part of the general theory of surfaces. In the same chapter, Dr. Molenbroek, by means of two new differentiating operators, obtains a simple symbolic representation for the first, second, and higher polars of a point with regard to a given surface. These remarks will indicate sufficiently the scope of a work which, though not altogether above criticism in minor details, is a distinct addition to quaternion literature, and deserves a wide circulation.

Colonel Hime's work is a much more modest production, being intended for the mere beginner. In general scope it might be compared to the first nine chapters of Kelland and Tait's "Introduction to Quaternions." The book contains many good examples in the simpler applications of quaternions to the geometry of triangle, plane, sphere, conic section, cone, &c., but it is less satisfactory in the exposition of the fundamental principles of the calculus. For example, the identification of unit vector and right versor is stated, but the reason for this identification is nowhere distinctly given. Again, the truth that the familiar Hamiltonian symbols $i\ j\ k$ may be regarded as in a sense *imaginaries*, because $i^2 = j^2 = k^2 = -1$, is supposed to lead to the equation

$$i = j = k = \sqrt{-1} = -i = -j = -k \text{ (Eq. 8, p. 40).}$$

This seems to be playing sad havoc with one's very definitions. Then on page 76 we find what is virtually the equation $\delta\beta^{-1}\delta = \gamma$ transformed into $\delta^2 = \gamma\beta$, the non-commutative principle being wholly ignored, and in consequence a quaternion and a scalar equated! These errors, especially the latter, are very surprising in a book whose author is a true disciple of Hamilton. Of minor blemishes we might refer to the appeal to Cartesian expansions in order to demonstrate (?) the associative principle in multiplication. Nor do we quite understand Colonel Hime's system of referring to authorities. For example, why should Prof. Hardy be quoted as the authority for the statement that every versor may be represented by a power of a unit vector; for is it not all in Hamilton (see "Elements," § 309)? Again, Dr. Odstrčil is credited with a proof that the three angles of a plane triangle are together equal to two right angles, the proof being an obvious particular case of Hamilton's remarkable expression for the product of the versor arcs of a spherical triangle. But surely the theorem regarding the angles of a plane triangle *underlies* the fundamental properties of quaternions and versors; so that the supposed proof is really reasoning in a circle. Dr. Odstrčil is worthy of higher praise than this. These blemishes apart, however, and leaving out of account the two errors already noted, we find in Colonel Hime's book a serviceable exposition of the elementary applications of quaternions. A careful study of its pages will go far to fit the reader for the arduous task of grappling with the higher and more characteristic developments to be found in the writings of the masters of the quaternion calculus.

OUR BOOK SHELF.

Sir Victor Brooke, Sportsman and Naturalist. By O. L. Stephen. (London: John Murray, 1894.)

THE late Sir Victor Brooke was an excellent example of a combination of sportsman and naturalist. In this book his life as a sportsman predominates; but a chapter on his researches in natural history, by Sir William Flower, shows that he possessed the keenness of observation required in a man of science. His most important contribution to science was an exhaustive paper, published in the *Proceedings* of the Zoological Society, the subject being the classification of the *Cervidæ*. At one time he was an enthusiastic student of natural history, but the state of Lady Brooke's health having compelled him to live out of England for the greater part of the year, he could not conveniently carry on his researches. From about 1880 his life was chiefly devoted to foreign travel and sport. The extracts from his letters and journals are full of stirring adventures, and contain some interesting observations on animal life and habits. Mr. Stephen prefaces these extracts with a memoir of his dead friend. The book is beautifully printed, and is illustrated by ten fine plates. It appeals particularly to those who were acquainted with Sir Victor Brooke, and who admired his character; nevertheless, such of the public as read it will find the contents interesting.

A Text-book of Dynamics. A Text-book of Statics. By William Briggs and G. H. Bryan. (The University Tutorial Series.) (London: W. B. Clive, 1894.)

THESE books belong to the elementary class, and a perusal of them shows that they will prove excellent additions to this series of useful text-books.

In both the authors have assumed little or no knowledge of trigonometry, and they have been written so that either may be read first. The treatment is conspicuous for its clearness and conciseness, and is all that a student about to enter a course could desire. The figures are neatly drawn, and many new ones are noticeable in the latter book.

Notwithstanding the fact that these text-books are published to meet the requirements of candidates for certain examinations, they may still be used by others, who are making themselves acquainted with these subjects. Besides several excellent series of examples, a very useful summary is added to each chapter, which will be serviceable for revision purposes. The adoption of different sizes and kinds of type, when it is, as here, carefully done, is also a very great boon to beginners.

The Slide-Rule. A Practical Manual. By Charles N. Pickworth, Wh.Sc. (London: Emmott and Co., Ltd., 1894.)

THE most modern form of slide-rule is of the Mannheim or Tavernier-Gravêt type, and undoubtedly surpasses its predecessors in many ways. At the present time this instrument is in general use on the continent, principally in France and Germany, and it is now becoming more popular in England.

The slide-rule may be defined as an instrument for mechanically effecting calculations by logarithmic computation. By its aid arithmetical, algebraical, and trignometrical processes may be performed much more quickly and with greater ease than by the ordinary methods, while the accuracy of the results are quite within the limits of error for all practical purposes. There is no doubt that when the instrument is better known, and its labour-saving property recognised, it will be more commonly seen in the laboratory and workshop than it is now. So many manipulations can be done with it that, without some guide, its full value cannot be appreciated. In the present little manual the author brings these all together, and in such a form that the reader can, by paying attention to the mechanical and mathematical principles, obtain an intelligent interest in the manipulations, and have confidence in the results.

W. J. L.

I Fondamenti Matematici per la Critica dei Risultati Sperimentali. Del Prof. P. Pizzetti. (Genova, 1892.)

AN elaborate memoir, of the nature of a complete treatise on the Method of Least Squares, in its application to the reduction to order of a long-continued series of experiments and of their numerical results.

It contains a valuable bibliography of writings on the subject, arranged alphabetically according to authors' names.

Hitherto the astronomer has made most use of this theory; but the artillerist is now finding it important for his purposes, in calculating from the number of hits to effect a desired amount of destruction the amount of ammunition required.

G.

Teppich-erzeugung im Orient. By various Contributors Pp. 204. (Wien: K. K. Österr.Handels-Museum, 1895.)

THIS work consists of a series of monographs on important antique tapestries contained in European museums and private collections, contributed by Sir George Birdwood, Mr. C. Purdon-Clarke, Mr. Vincent J. Robinson, Mr. S. J. A. Churchill, Dr. W. Bode, M. Gerspach, and M. O. M. Stoeckel. In addition to the history of antique tapestries, the work contains descriptions of a number of the more important types of modern tapestries of the Levant, Persia, and India. The illustrations are numerous and of high quality.

A Laboratory Manual. By W. R. Orndorff, A.B., Ph.D. (Boston: D. C. Heath. London: Isbister and Co., 1894.)

A COURSE of experiments in organic chemistry, systematically arranged as an adjunct to Prof. Ira Remsen's work on the "Compounds of Carbon." As Dr. Orndorff has had a large experience in the laboratory work to which the book refers, the conditions of the experiments described can be depended upon, which is the highest recommendation that can be given to a manual of this kind.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Finger-Prints.

I HAVE been quite unable, since I saw Mr. Faulds' letter in your issue of October 4, to take the matter of it in hand hitherto; and I do so now only because I think Mr. Faulds is entitled to raise the question if he pleases. To the best of my knowledge, Mr. Faulds' letter of 1880 was, what he says it was, the first notice in the public papers, in your columns, of the value of finger-prints for the purpose of identification. His statement that he came upon it independently in 1879 (? 1878) commands acceptance as a matter of course. At the same time I scarcely think that such short experience as that justified his announcing that the finger-furrows were "for-ever-unchanging."

How I chanced upon the thing myself in 1858, and followed it up afterwards, has been very kindly stated on my authority by Mr. Galton, at whose disposal I gladly placed all my materials on his request. Those published by him are only a part of what were available. (See his "Finger-Prints," page 27, and his "Blurred Finger-Prints.") To what is there stated I need now only add, at Mr. Faulds' request, a copy of the demi-official letter which I addressed in 1877 to the then Inspector-General of Jails in Bengal. That the reply I received appeared to me altogether discouraging was simply the result of my very depressed state of health at the time. The position into which the subject has now been lifted is therefore wholly due to Mr. Galton through his large development of the study, and his exquisite and costly methods of demonstrating in print the many new and important conclusions he has reached.

I take the opportunity, in reference to a late article on Anthropometry (in the *Nineteenth Century* of September 1894, p. 365), to deprecate, as being to the best of my knowledge wholly unproved, the assertion that the use of finger-marks in this way was "originally invented by the Chinese." I have met no evidence which goes anywhere near substantiating this. As a matter of fact, I exhibited the system to many passengers and officers of the P. and O. steamship *Mongolia* in the Indian Ocean, during her outward voyage in February 1877; and I have the finger-prints of her captain, and of all those persons, with their names. It is likely enough that the idea, which caught on rapidly among the passengers, may have found a settlement in some Chinese port by this route, and have there taken a practical form; but whether that be so or not, I must protest against the vague claim made on behalf of the Chinese, until satisfactory evidence of antiquity is produced.

Littlemore, November 7. W. J. HERSCHEL.

(TRUE COPY OF OFFICE COPY.)

Hooghly, August 15, 1877.

MY DEAR B——.—I enclose a paper which looks unusual, but which I hope has some value. It exhibits a method of identification of persons, which, with ordinary care in execution, and with judicial care in the scrutiny, is, I can now say, for all practical purposes far more infallible than photography. It consists in taking a seal-like impression, in common seal ink, of the markings on the skin of the two forefingers of the right hand (these two being taken for convenience only).

I am able to say that these marks do not (bar accidents) change in the course of ten or fifteen years so much as to affect the utility of the test.

The process of taking the impression is hardly more difficult than that of making a fair stamp of an office seal. I have been trying it in the Jail and in the Registering Office and among pensioners here for some months past. I have purposely taken no particular pains in explaining the process, beyond once showing how it is done, and once or twice visiting the office, inspecting the signatures, and asking the *omlah*[1] to be a little more careful. The articles necessary are such as the *daftari*[2] can prepare on a mere verbal explanation.

Every person who now registers a document at Hooghly has to sign his "sign-manual." None has offered the smallest objection, and I believe that the practice, if generally adopted, will put an end to all attempts at personation.

[1] Clerks. [2] Man in charge of stationery.

The cogency of the evidence is admitted by every one who takes the trouble to compare a few signatures together, and to try making a few himself. I have taken thousands now in the course of the last twenty years, and (bar smudges and accidents, which are rarely bad enough to be fatal) I am prepared to answer for the identity of every person whose "sign-manual" I can now produce if I am confronted with him.

As an instance of the value of the thing, I might suggest that if Roger Tichborne had given his "sign-manual" on entering the Army on any register, the whole Orton case would have been knocked on the head in ten minutes by requiring Orton to make his sign-manual alongside it for comparison.

I send this specimen to you because I believe that identification is by no means the unnecessary thing in jails which one might presume it should be. I don't think I need dilate on that point. Here is the means of verifying the identity of every man in jail with the man sentenced by the court, at any moment, day or night. Call the number up and make him sign. If it is he, it is he; if not, he is exposed on the spot. Is No. 1302 really dead, and is that his corpse or a sham one? The corpse has two fingers that will answer the question at once. Is this man brought into jail the real Simon Pure sentenced by the magistrate? The sign-manual on the back of the magistrate's warrant is there to testify, &c.

For uses in other departments and transactions, especially among illiterate people, it is available with such ease that I quite think its general use would be a substantial contribution towards public morality. Now that it is pretty well known here, I do not believe the man lives who would dare to attempt personation before the registrar here. The *mukhtears*[1] all know the potency of the evidence too well.

Will you kindly give the matter a little patient attention, and then let me ask whether you would let me try it in other jails?

The impressions will, I doubt not, explain themselves to you without more words. I will say that perhaps in a small proportion of the cases that might come to question the study of the seals by an expert might be advisable, but that in most cases any man of judgment giving his attention to it cannot fail to pronounce right. I have never seen any two signatures about which I remained in doubt after sufficient care.

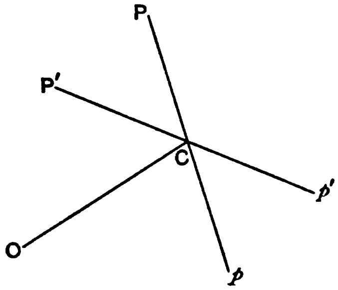
Kindly keep the specimens carefully.

Yours sincerely,
W. HERSCHEL.

Boltzmann's Minimum Function.

MR. CULVERWELL, in his letter to NATURE of October 25, questions the existence of Boltzmann's minimum function, and asks will somebody tell us what the H-theorem really proves?

As I have made use of the theorem on several occasions, I may be permitted to say a word in its defence. I will endeavour to answer Mr. Culverwell's question what the theorem proves for the simple case of equal elastic spheres. If I can do that, it will probably not be difficult to generalise the result.



Let then V, or OC in the figure, denote the velocity of the common centre of gravity of two elastic spheres, each having diameter c. Let R be their half relative velocity. If we describe a spherical surface with radius R about centre C, and if Pp be any diameter of it, the actual velocities of two spheres are OP and Op.

Let the number per unit of volume of spheres whose velocities are represented by lines drawn from O to points within the element of surface dS at P be denoted by FdS. Let fdS denote the corresponding number for the element dS at p. Then FfdS is the number of pairs whose relative velocity R falls within the cone described with solid angle dS about PCp as axis. Let P′Cp' be any other diameter, and let F′dS′, $f'd$S′ be the corresponding number of spheres with velocities OP′ and Op'.

If a pair of spheres collide the relative velocity assumes, as the result of collision, a new position only, and what that position shall be depends on the coordinates of the collision, *i.e.* the point in which a line parallel to the relative velocity through the centre of one sphere cuts a circular area of radius c, drawn through the centre of the other sphere at right angles to that line. If the collision coordinates be taken at random, then the following condition holds, viz.:—For any given direction of R before collision, all directions after collision are equally probable. Call that condition A.

Now assume condition A to be fulfilled, and consider all collisions which take place between pairs of the V R spheres.

The number which after the collisions belong to the class FfdS will be on the above assumption $\frac{dS}{4\pi}\iint F'f'dS'$.

But before the collisions it is FfdS. Therefore, as the result of collisions it is increased by $dS\left(\frac{\iint F'f'dS'}{4\pi} - Ff\right)$. That is by $\frac{dS}{4\pi}\iint (F'f' - Ff)dS'$, F$f$ being treated in the integration as constant.

Therefore

$$\frac{dF}{dt} = \frac{df}{dt} = \frac{\pi c^2 R}{4\pi}\iint (F'f' - Ff)dS'$$

and if

$$H = \iint f(\log f - 1)dS,$$

$$\begin{aligned}\frac{dH}{dt} &= \frac{\pi c^2 R}{4\pi}\iint dS\iint (F'f' - Ff)\log(Ff)dS' \\ &= \frac{\pi c^2 R}{4\pi}\iiiint dS dS'(F'f' - Ff)\log(Ff) \\ &= \frac{\pi c^2 R}{4\pi}\iiiint dS dS'(Ff - F'f')\log F'f' \text{ by symmetry} \\ &= \tfrac{1}{2}\frac{\pi c^2 R}{4\pi}\iint (F'f' - Ff)\log\frac{Ff}{F'f'}dS dS',\end{aligned}$$

which is necessarily negative if not zero. The above is true for all values of V and R, and therefore for the whole system.

Thus we have proved that if condition A be satisfied, then if all directions of the relative velocity for given V are not now equally likely, the effect of collisions is to make H diminish.

The objection that I understand to be made is that if you reverse all the velocities after collisions, the system will retrace its course with H increasing—which is supposed to be contrary to the thing proved.

The objection is wrong because in your reverse motion condition A is not fulfilled. The proof (is not wrong but) ceases to be applicable by failure of the condition on which it is based.

Somebody may perhaps say that by this explanation I save the mathematics only by sacrificing the importance of the theorem, because I must (it will be said) admit that there are, after all, as many cases in which H increases as in which it diminishes. I think the answer to this would be that any actual material system receives disturbances from without, the effect of which, coming at haphazard, is to produce that very distribution of coordinates which is required to make H diminish. So there is a general tendency for H to diminish, although it may conceivably increase in particular cases. Just as in matters political, change for the better is possible, but the tendency is for all change to be from bad to worse. S. H. BURBURY.

1 New Square, Lincoln's Inn, November 12.

The Kinetic Theory of Gases.

I CANNOT quite agree in Mr. Bryan's remembrance of what took place in the discussion of the Thermodynamics Report at Oxford. As far as I recollect, Prof. Boltzmann's reply was not in special reference to such a point as the specific heats of gases, but was in answer to a very vigorous, if somewhat general, onslaught of Prof Fitzgerald, who simply stated that it appeared evident from the spectra of gases and other considerations, that the energy could not be equally divided among all the degrees of freedom of the coordinates, and said what he wanted to know from Prof. Boltzmann was *when the theory*

[1] Attorneys.

became inapplicable, what assumptions became invalid?—why, if Dr. Watson's method of generalised coordinates were valid, the ether, the solar system and the universe generally were not subject to the Maxwell-Boltzmann law, so that the mean kinetic energy of every coordinate in the universe should be the same and so on, insisting that what he wanted to know was *why the theory failed, what* assumptions were invalid.

After the other speakers had concluded, Prof. Boltzmann arose to reply, and he took up a perfectly logical position. He said that the theory as it left his hands was a mathematical theorem, a piece of pure mathematics, and that it was for *physicists* to say how far it applied to gases—that the reason of any disagreement between the theory and the facts was "a mystery, as Lord Salisbury had said."

That appears an unassailable position, and the only misapprehension which, so far as I can see, could arise, would be that Boltzmann had admitted not only that his work was a piece of pure mathematics, but that it was *nothing more*, a bare theorem without the promise that future adaptations would lead to an even closer accord between the theory and the facts. If such an impression as that has got abroad, Mr. Bryan has done good service in calling attention to the matter.

There seem many difficulties about the suggestion (made by Dr. Larmor at Oxford, and referred to by Mr. Bryan in his letter) that the spectra of gases need not be explained by the Boltzmann law, as they arise not from molecular but from ethereal vibrations set up by the molecules. Surely if so, the molecules cannot be regarded as an independent system, and Dr. Watson's generalised coordinates must include ethereal coordinates also, and the Maxwell-Boltzmann law must be supposed to hold for matter and ether alike, which does not seem to get over the difficulty.

November 10. EDWD. P. CULVERWELL.

Homogeneity of Structure the Source of Crystal Symmetry.

MR. BARLOW's letter on this subject (p. 58) raises a problem of considerable interest, which may be stated in simple words.

He has inquired in the most general manner possible how anything can be uniformly distributed in space so as to constitute a homogeneous system; the word homogeneous may be taken to signify that round any one member of the system the distribution of the remainder is the same as round any other. It is not necessary to say that the units of which the system consists are figures or solids, but merely that, whatever the unit may be, it is homogeneously repeated.

Now repetition may conceivably take place by sliding the unit from one position to another, by rotating it about an axis, by reflecting it across a plane, or by a combination of these processes; in other words, by translation, rotation, and inversion. If the last process be excluded, we cannot arrive at all the types of symmetry presented by crystals; if it be included, we obtain all those types and no others. Therefore the crystal structure is one in which this process is operative. Mr. Barlow himself does not include inversion as a mode of homogeneity, but regards it as an additional property possessed by some crystal structures. Earlier writers have specialised the problem by taking a particular unit. Bravais and Sohncke, for example, to whom the modern treatment of the subject is entirely due, have investigated systems of points. Now the reflection of a point is an identical point, so that it is useless to introduce the principle of reflection or inversion as distinct from translation in order to derive any *one* point of such a regular system from another. The same is true of spheres and many symmetrical figures, and unfortunately molecules have usually in such investigations been treated as points or spheres or symmetrical figures.

Mr. Barlow does not consider that his solution of the geometrical problem supplies a theory of crystal structure or settles the question whether the seat of the symmetry is in the arrangement or in the configuration of the molecules.

But it appears to me that a step of very great importance has been made, for, surely, these investigations prove that the symmetry of such a structure *can* be entirely explained by the arrangement of the units. I would go farther, and ask whether the result does not suggest that the units which determine the symmetry of a crystal are units capable of repetition by the processes of translation, rotation, and inversion. If this be so, we are not justified in treating them generally as points or as symmetrical figures.

Many things besides unsymmetrical figures can be conceived which are capable of such repetitions; for example, a solenoid, a vortex motion, a system of forces in statical equilibrium.

I would add that Mr. Barlow's investigation cannot be said either to support or to contradict the theories of Fedorow and Schönflies; it is, as he remarks, purely geometrical, and in this respect is identical with their researches, and leads to the same results. It is true that Fedorow has proposed a theory of crystal structure, but this is only an application of the geometrical principles which he had previously established.

H. A. MIERS.

British Museum (Natural History), November 19.

Gravitation.

I REGRET that I cannot agree with Dr. Joly's suggestion (*vide* p. 57 *supra*) that the curious adhesion which I observed between solids immersed in a stretched liquid, lends itself to any explanation of gravitation on the lines that he indicates. The phenomenon is, and was described by me as, one of *adhesion*, and not, as Dr. Joly puts it, of *attraction*, for there was no evidence of any approach of bodies separated by a measurable thickness of liquid, and there is, further, no reason to suppose that the phenomenon would occur unless the medium were already modified in the neighbourhood of the solid surfaces, *i.e.* unless a condition which we may provisionally ascribe to gravitation already existed. For this reason Dr. Joly's suggestion appears to me to be an invitation to argue in a circle.

If there were evidence, which there is not, that the ether round celestial bodies was modified to a great distance, the suggestion would, I think, be legitimate, but it would then be necessary to explain the modification.

Devonport, November 18. A. M. WORTHINGTON.

The Foucault Pendulum Experiment.

PROF. GREENHILL gives currency to quite an erroneous idea in last week's NATURE (p. 50). He says "in the Foucault experiment of the pendulum which shows the rotation of the earth, the slightest current of air will destroy and reverse the desired motion; so that it is advisable in showing the experiment to have an elastic ball concealed in the palm of the hand, which can send a slight current of air on the bob of the pendulum, and thus accelerate the initial precession of the plane of the vibration so as to gratify the eyes of the audience and diminish their impatience at the slowness of the motion." If Prof. Greenhill will go to the Western Galleries of the South Kensington Museum any day, he will be able to see a Foucault pendulum fulfilling its purpose without being particularly protected from draughts, and without the accessory puffs to which he refers. The pendulum is suspended in a place where people are continually passing to and fro, yet its plane of vibration always rotates in the same direction as watch-hands, or rather the table under the pendulum turns in the opposite direction. I have watched the pendulum dozens of times without seeing it fail. G. A. R.

November 19.

An Observation on Moths.

AN experiment was tried in 1894, on a number of pupæ of *Samia promethea* and *Samia cecropia*, which brought out a point of which I have seen no mention. When the moth is almost ready to burst through the thin shell which encloses it, this outer skin becomes dark-coloured and friable, and the insect can often be seen moving within.

If the enclosing envelope is then removed with a scalpel and forceps, the moth struggles out, apparently as lively as when legitimately hatched.

The only hitch in the proceedings seems to be in the non-expansion of the wings, the development of which usually takes place at once. The moth crawls about, like a forlorn penguin, for a period varying from one to three days, when the wings seem to realise the absurd state of affairs, and make a brave effort to fulfil their part of the contract. The effort, however, is only partially successful, for owing to their dry condition the expansion is irregular and incomplete, and the poor moth remains a helpless cripple.

This would seem to demonstrate that the wings do not mature as rapidly as the rest of the body, and that until complete maturity is reached, no effort towards expansion is made.

L. C. JONES.

PHOTOGRAPHS OF A TUMBLING CAT.

M. MAREY'S recent photographs of a falling cat, taken with the view of determining the mechanical conditions which enable the animal to alight on its feet, have excited considerable interest. Figs. 1 and 2 accompanied his paper on the tumbling of cats, presented to the Paris Academy, and are reproduced in *La Nature*. The former gives a side view of pussy, and the latter a back view. The cat was held by its feet, and was let go in that position. In each of the pairs of figures, the series of images runs from right to left, and the lower is a continuation of the upper. The expression of offended dignity shown by the cat at the end of the first series indicates a want of interest in scientific investigation.

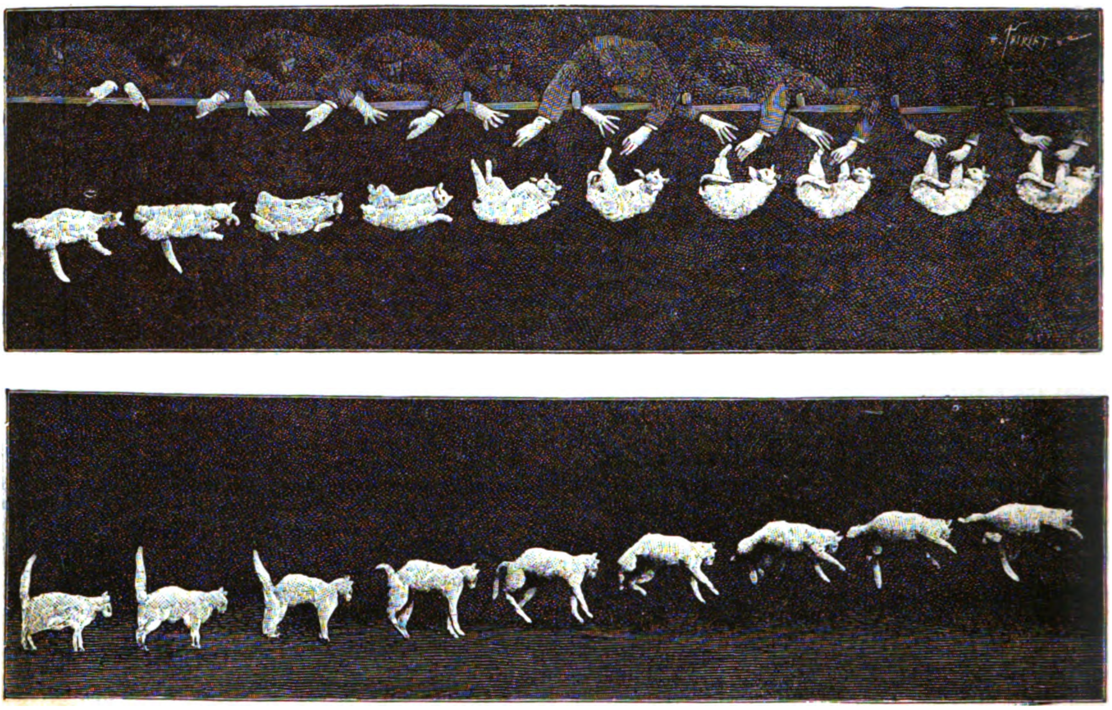


FIG. 1.—Side view of a falling cat. (The series runs from right to left.)

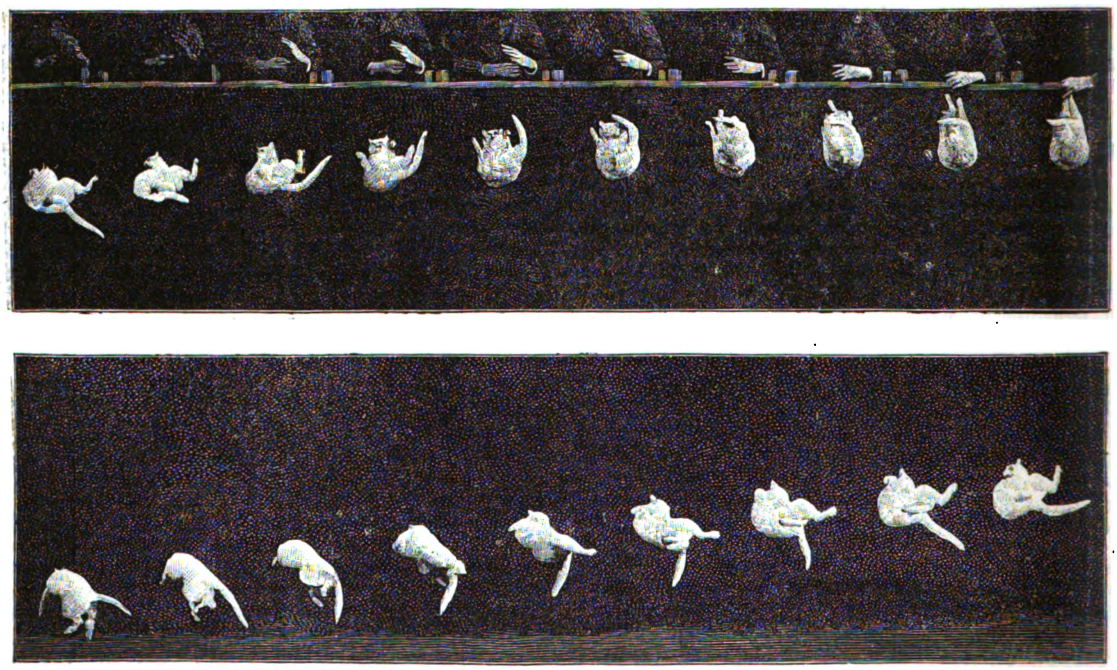

FIG. 2.—End view of a falling cat. (The series runs from right to left.)

The rotation of the fore and hind parts of the cat's body takes place at different stages. At first the twist is almost exclusively confined to the fore part, but when this amounts to about 180 degrees the rear part of the animal turns. M. Marey is of the opinion that an inspection of the figures altogether excludes the idea that the animal uses the hands that let it go as a fulcrum by means of which a movement of rotation is obtained. The first few images in each of the two series show that at the beginning of the fall the cat exhibits no tendency to turn either one side or the other.

As to the hypothesis that the resistance of the air affords a means of turning, this also appears to be inadmissible; because, on account of the tumbling motion of the animal, if this resistance had an appreciable effect, it would produce a rotation in the opposite direction to that observed.

M. Marey thinks that it is the inertia of its own mass that the cat uses to right itself. The torsion couple which produces the action of the muscles of the vertebra acts at first on the forelegs, which have a very small motion of inertia on account of the front feet being foreshortened and pressed against the neck. The hind legs, however, being stretched out and almost perpendicular to the axis of the body, possesses a moment of inertia which opposes motion in the opposite direction to that which the torsion couple tends to produce. In the second phase of the action, the attitude of the feet is reversed, and it is the inertia of the forepart that furnishes a fulcrum for the rotation of the rear.

BIOLOGY IN THE UNITED STATES—A PROSPECT.[1]

THIS volume is slightly larger than its predecessor published in 1891, and is an advance upon it in the number and class of its illustrations. During the interval of publication of the two volumes, much of the work announced in the first one has appeared in full; and the present one shows that although, perhaps, more might be made of the resources of the Wood's Holl Laboratory and its rich surroundings by a better appreciation on the part of the scientific public, there is no falling off in either the energy or enthusiasm of its founders and chief supporters. The ten lectures reported in this volume are chiefly special ones, given by investigators who undertake to review their chosen field of labour, and to set forth the results of their own inquiry —it being an avowed object to bring forward unsettled problems of the day, and discuss them freely. The lectures are published for the first time, with the exception of that which is the most striking of the series and one of the most remarkable contributions to recent biological literature, viz. Prof. C. O. Whitman's thesis on "The Inadequacy of the Cell-theory of Development," originally read before the Zoological Congress of the World's Columbian Exposition, and already reprinted in the *Journal of Morphology*. Prof. Whitman's work in this department dates from his inaugural dissertation for the degree of Doctor of Philosophy in the University of Leipzig, dealing with the embryology of *Clepsine*, in which he laid the foundation of his now famous teloblast theory. The researches which this essay has provoked rank foremost in interest among all those recently devoted to the study of the germinal blastemata.

No one has more assiduously followed up Prof. Whitman's suggestive lines than Prof. E. B. Wilson, whose lecture on "The Mosaic Theory of Development" ranks first in order in the present volume. His recent work on the cell-lineage of *Nereis* is second only to that of Whitman in interest and importance. His present treatise is a review of the embryological work of the last decade in its bearing upon the biogenetic law. Prof. Whitman would seek the secret of organisation in ultimate elements of living matter "for which *idiosomes* seems an appropriate name"; Prof. Wilson, that of differentiation during development in the interaction of the embryo-cells. There next follows a lecture by Dr. E. G. Conklin, on "The Fertilisation of the Ovum," *apropos* of the author's researches into the development of the marine gasteropod *Crepidula plana*.

Lecture iii. is by Prof. Jacques Loeb, "On some Facts and Principles of Physiological Morphology." He first considers the question of "heteromorphosis" or substitution of organs, as illustrated (under the maltreatment of *Antennularia*) by the development of new roots and apices in relation to gravitation, and by root formation at points of contact with solid bodies, in *Margeliss* and other hydroids. He shows that it is possible to obtain roots and polyps at will over various and interchangeable areas, in direct response to modified conditions of growth. There follows this a lecture by Prof. Ryder on "Dynamics in Evolution," which is suggestive but imaginary. New terms and statements of probabilities it does contain, but new facts it does not. Its most interesting portions are those relating to surface tension in its probable bearings on protoplasmic activity; but it appears to us rather more sensational than sound. The comparison of the behaviour of a contracted smoke-ring to an amœba in motion is suggestive, perhaps in a sense not intended by the author. Dr. Watasê follows with a dissertation "On the Nature of Cell Organisation."

Lecture vii. is a very welcome one, by Dr. Howard Ayers, on *Bdellostoma Dombeyi*, *apropos* of its author's work upon the comparative morphology and physiology of the vertebrate ear. He deals at some length with the habits of the animal, and adduces additional evidence for the belief in the primitive, as distinguished from the alleged "by parasitism degenerate" nature of the cyclostomi which has been so generally accepted. He records the fact that the gills vary in number from eleven to thirteen on either side, in individuals from different localities; he regards this variation as indicative of suppression, and the numerically highest as the most primitive type, instituting comparisons with the larval *Amphioxus* which appear to us unsound. We welcome his conclusion that the numerical variation of the gills has nothing to do with the formation of the ductors œsophago-cutaneus. He provisionally argues that *Bdellostoma* is unique in the fact that geographical distribution has had little or no effect upon its anatomical structure; and proposes to recognise but a single genus and species of this form, in a manner curiously mindful of his notorious attempt to similarly unite *Protopterus and Lepidosiren*. Not even allowing for the possibility that the hitherto accepted species of Bdellostomas may be distinct in their habits as well as taxonomically, this proposal appears to us premature, and systematic ichthyologists will certainly not acquiesce to it. In common with most subsequent investigators, he finds himself unable to confirm Beard's alleged discovery of calcified teeth in these creatures. He regards Beard's "bone" as "much hardened horn, produced by the methods used in preparation." This we cannot accept. The cells of Beard's "calcified teeth," although uncalcified, are mesoblastic, and the structure described by him as an "enamel cap" (whatever it may be) certainly does appear in individual sections. He finds that hermaphrodites occur even among old individuals; but while examples possessed of ripe ova and spermatozoa may be forthcoming, he finds them to be rare, and concludes that preponderance of *males* is the ordinary condition. His observations upon the olfactory organ

[1] "Biological Lectures delivered at the Marine Biological Laboratory of Wood's Holl." Vol. ii. (Boston: Ginn and Co., 1894.)

have led him to the belief in the paired nature of the cyclostome nose, but they are curiously at variance with those of Von Kupffer that have lately led to the opposite conclusion. His remarks upon the functions of the thread-forming type of cutaneous gland are particularly welcome, in correlation with Weymouth Reid's work upon the origin and constitution of the thread substance. Concerning the ear, he records the striking result that while removal of one labyrinth leads to marked disturbances in the equilibrative function, on the removal of both ears all trace of such disturbance disappears. Morphologists and physiologists will await with interest the full edition of this important communication.

Lectures viii. and ix. are botanical, and as unequal in merit as any two in the whole work. One of them, by Prof. Muirhead Macfarlane, on "Irrito-contractility in Plants," is a record of some beautiful and striking experiments, a very charming one being that with a block of ice, from which he has drawn the conclusion that displacement of the *Oxalis* leaf under its action is the effect of cold and not of weight. The author reverts to his earlier observation, no less beautiful and striking, that in order to induce the closure of the *Dionæa* leaf the application of two successive stimuli within proper intervals is necessary. He deduces two leading principles—(1) that plants, like animals, being in a condition of protoplasmic continuity, are, by virtue of it, possessed of a power of general contractility; and (2) that the positions taken up by the *Oxalis* and other leaves under the action of the tropical sun are due to heat and not light effects. The other lecture, by Prof. W. P. Wilson, on "The Influence of External Conditions on Plant Life," contains little new, and is in part vague and unintelligible.

The volume closes with an illustrated report on "The Marine Biological Stations of Europe," by Dr. Bashford Dean, and an appendix on "The Work and the Aims of the Marine Biological Laboratory" at Wood's Holl, by Prof. Whitman, giving a list of close upon 100 papers produced under its auspices.

It cannot have escaped the reader's notice that the contents of the book are largely reports upon experimental work which bears directly upon the recent theories of Weismann, so popular in our own land. Contemporaneously with the labours of Wilson and Loeb, of which an account is given in its pages, the work of Driesch, Herbst, and others, which carries us back through that of Vejdovský, Chun, and Chabry, to the classical observation of Hæckel, now twenty-five years old, that detached portions of the fully segmented ovum (of the Siphonophoran *Crystallodes*) may give rise to young animals, have materially modified our conception of certain fundamentals of embryology. The observation that variation in development, "twinning," and other kindred phenomena, may bear a definite relationship to variation in temperature, chemical composition, and osmotic pressure of the surrounding medium, is now well established. The discovery that after the removal of either the micromeres or macromeres, the segmenting embryonic mass may still form a gastrula—that the differentiation of outer layer cells to form certain larval organs may be directly a question of location—and that certain blastomeres if separated at the two-celled stage may each give rise to an embryo one-half size, and if isolated at the four-celled stage to one of one-fourth size, is very extraordinary; and, viewing the situation generally, one is prone to ask where now *are* the said theories? Concerning them, Prof. Wilson replies "the fine spun thread . . . leads us little by little into an unknown region, so remote from the *terra firma* of observed fact that verification and disproof are alike impossible." The theories of Weismann were originally framed with the laudable desire of stimulating inquiry. They do not seek to explain the actual *modus operandi* of the hereditary process so much as to localise the seat of hereditary tendency and influence. The implication that neither proof nor disproof are possible, applies, for the matter of that, to even the theory of descent with modification *versus* that of special creation. The educated mind has, however, upon purely logical grounds, chosen between the alternatives in this instance, and it may be safely relied upon to do so in the other.

G. B. H.

NOTES.

THE anniversary meeting of the Royal Society will be held on Friday, November 30.

AT the first monthly meeting of the Royal Statistical Society for the present session, held on Tuesday afternoon, a gold Guy Medal was presented to Dr. Robert Giffen, C.B., F.R.S., in recognition of his long and exceptional services to statistical science.

M. LOUIS FIGUIER, who died on November 8, was an eminent populariser of the results of scientific research. He was born at Montpellier in 1819, where he took his degree of Doctor of Medicine in 1841. A few years later he became Professor of Pharmacy in the Paris École de Pharmacie. In 1850 he took his degree as Doctor of Science at Toulouse. He published some important memoirs on chemical subjects, but will be remembered chiefly for his numerous works on popular science. Since 1856, he issued every year the *Année Scientifique*, in which he summarised the most interesting and important scientific discoveries of the year.

THE Manchester correspondent of the *Lancet* says that the sum of £783 10*s*. 3*d*. has been raised for the fund in memory of the late Prof. Milnes Marshall, and after expenses £760 2*s*. 3*d*. will be left. Of this sum £650 have been invested in Manchester Corporation Stock to provide for the maintenance of the Marshall Biological Library given to the Owens College by the relatives of Prof. Marshall, while £102 8*s*. 6*d*. have been similarly invested to provide a "Marshall Gold Medal" to be annually competed for at the Owens College athletic sports.

DR. J. SCHEINER, of the Potsdam Astro-Physical Observatory, has been appointed Extraordinary Professor in Berlin University.

A SEVERE earthquake occurred on Friday last in Sicily and Southern Italy. The shocks were felt not only in the city and district of Messina, and several other places in Sicily, but also throughout the province of Reggio di Calabria, in Southern Italy. The disturbance was also recorded upon the seismic instruments at Rome and Ischia. Shocks of more or less violence were felt at Palmi, Seminara, Santa Eufemia, and San Procopio, in the province of Reggio di Calabria. The centre of the disturbance in this province appears to have been in the west, round the towns of Palmi and Bagnara. San Procopio, a town near Palmi, has been almost entirely destroyed, and it is estimated that at least two hundred persons have perished at that place alone. Since Friday the district of Reggio di Calabria has been slightly disturbed, but these tremors have not caused any further damage.

THE Drapers' Company have contributed £20 to the funds of the Epping Forest Museum, now being formed in Queen Elizabeth's Lodge, Chingford, by the Essex Field Club, under the sanction of the Epping Forest Committee of the Corporation of London. The museum is intended to illustrate the natural history, antiquities, and scenery of this beautiful district.

THE *Weekly Weather Report* of the 17th instant shows that in many districts the rainfall greatly exceeded the mean; over all the southern counties of England the amount was nearly four times as much as the average. The largest amounts recorded at individual stations during the week were 6·25 inches at Godmanstone (near Dorchester), 5·51 inches at Scilly, 5·13 inches at Killarney, and 4·70 inches at Falmouth, while 4·60 inches fell at Crowborough, Sussex, in six days. The rainfall since the beginning of the year has now exceeded the average in all districts, except the Midland Counties and the west coast of Scotland. The excess in the south of England and south of Ireland amounts to over five inches.

REPORTS in the medical papers show that the enthusiasm roused in France by the results of the anti-toxin treatment of diphtheria has by no means abated. We learn from the *British Medical Journal* that the administrative Society of the Sauveteurs de la Seine have presented M. Roux with the Grand Diplôme d'Honneur. The Var General Council has voted an equivalent of £40 for the Pasteur Institute, and £80 towards creating a similar institute at Marseilles. The Lille Municipal Council has declared for the erection of a diphtheria laboratory, and has opened a subscription in order to collect the necessary funds. The city of Lille has subscribed £1000. The Council has undertaken to furnish from £1400 to £1600 for a municipal bacteriological laboratory. The Havre municipality has voted £200 towards the cost of establishing a laboratory for the preparation of anti-diphtheric serum. The Paris correspondent of the *Lancet* reports that the Municipal Council of Paris has voted a subvention of fifteen thousand francs to the Pasteur Institute in aid of the preparation and distribution of anti-toxin. A sum of seven thousand six hundred francs has also been voted for the erection of accommodation for immune horses, and an allowance of fifteen hundred francs has been made to enable the institute to prepare and distribute anti-diphtheric serum during the present month and the month of December. In our own country, Sir Joseph Lister's appeal for funds has resulted in the sum of £850 being raised. It is estimated that at least £2000 will be required by the British Institute of Preventive Medicine in order to establish an installation for the manufacture of a sufficient quantity of the fluid to supply the demand.

A MARINE laboratory founded and maintained by a religious corporation, is probably unique of its kind; but such is the case with the Russian station on the island of Solowetzk, in the White Sea, as an interesting article in *Die Natur* informs us. From the early part of the fifteenth century Solowetzk or Holy Island has been the seat of an important monastery, but the foundation, in 1881, of a marine laboratory in connection with it was principally due to the efforts of Prof. R. Wagner, of St. Petersburg, and to the friendly offices of the late Archimandrite Mileti. The laboratory results from the conversion of a herring factory already existing there on a favourable site. It is now a convenient two-storied building, furnished with tank-room, museum, and six work-rooms with large windows, fully provided with all necessary utensils and reagents. Perpetual day is enjoyed from the middle of May to the middle of July, and during that period the energetic naturalist can work continuously with his microscope night and day, if he so pleases. A little fleet of sailing-boats is at the disposal of the station, but, owing to the uncertainty of the winds, a steam-launch is found to be a great desideratum. The attendants are selected from the peasants serving longer or shorter periods in the monastery, and the laboratory naturally suffers a good deal of inconvenience from the frequent changes which ensue. The director for some three years past has been M. Knipowitsch, whose local knowledge has considerably facilitated the researches of visiting naturalists. A long deep lagoon on the east of the island presents features of unusual interest to the biologist. Owing to its physical conformation the lower layers of water remain throughout the year at a constant low temperature, enabling such Arctic forms as *Yoldia arctica* to survive through the summer heat; while the warming of the tidal surface waters in summer favours the development of such forms as *Cyprina islandica*, and markedly hastens the development of medusæ such as *Cyanea* and *Aurelia*. Solowetzk may be reached from St. Petersburg either *viâ* Jaroslaw and Archangel, or, more directly, *viâ* the lakes, Povjonetz and Szumski.

CAPTAIN WIGGINS, who had left the Yenesei in the *Stjernen*, late in the season for England, has been wrecked in Yugor Strait, but a telegram from Archangel states that all on board are well. Particulars have not yet been received, but the fact points to a serious condition of the ice in the Kara Sea.

THE Christmas Lectures to Young People, arranged by the Royal Geographical Society, will this year be delivered by Dr. H. R. Mill. The course, entitled "Holiday Geography," will include four lectures, dealing respectively with maps as holiday companions; geographical pictures, with special reference to amateur photography; a neglected corner—the English lakes; and a geographical holiday on the edge of the Alps. The lectures will take place in the map-room of the Royal Geographical Society, and will be profusely illustrated by the lantern.

THE Royal Geographical Society initiated the new technical meetings for geographers on Monday afternoon, by the discussion of a paper on a pre-Columbian discovery of America, by Mr. Yule Oldham. The claim for the discovery of Brazil by a Portuguese navigator in 1447 was based on a map of Andrea Biancho prepared in 1448, on which an "authentic island 1500 miles west of Cape Verde" was shown. This evidence was supported by various additional arguments, including the St. Brandan's Island of Martin Behaim's globe of 1492. A very lively discussion ensued, in which Mr. E. G. Ravenstein, Mr. Payne, Mr. Beazeley, Dr. Schlichter, Mr. Delmar Morgan, and others took part. The general conclusion of the meeting was unfavourable to the view of the early discovery of Brazil, but all speakers united in expressing their admiration of the manner in which Mr. Oldham marshalled the facts and expounded his theory.

DR. ADOLF E. FORSTER, of Vienna, has made a very careful study of the temperature variations in the rivers of Central Europe, which has just been published in Prof. Penck's *Geographische Abhandlungen*. He has collected a great number of isolated sets of observations, in several cases extending over many years, which have been made by different observers on the main rivers and tributaries of the Vistula, Oder, Elbe, Weser, Rhine, Danube, Adige, Po, Rhone, Loire, Seine, and Thames. These are discussed in order to bring out the amount of diurnal range, the effect on the mean result of different methods of observations (including the effect of depth), the relation between the temperature of water and air in different classes of rivers, the annual march of river-temperature, the variability of water-temperature from the long-period means, the influence of ice, and various other factors, such as the effect of dynamical heating on account of fall from higher to lower levels. Dr. Forster recognises the necessity of farther observations of a strictly comparable kind in order to obtain sure results, especially with regard to the bearing of river-temperature on meteorology; but the results he has obtained are of great interest. He shows how the relation of air- and water-temperature depends on the character of the water-surface considered. In glacier-fed rivers the air is colder than the water only for four months in winter and early spring; in summer the maximum temperature of air and water coincides with the greatest excess of air-temperature. A similar though less marked relation holds good for mountain streams which are not fed by glaciers. In lakes and the outlets of lakes the air-temperature is higher than that of the water only during the four months during which heat is being stored, th curves crossing close to the maximum. In rivers flowing over plains, such as the Oder at Breslau, and the Marne at its junction with the Seine, the water-temperature remains throughout the year from one to three degrees Centigrade warmer than t he

HERR E. LECHER, in the *Wiener Berichte*, gives an account of an experiment he has performed to test whether when a magnet turns about its magnetic axis the lines of force remain at rest or turn with the magnet. A magnet is divided by an equatorial plane into two parts, which can turn independently. Under these circumstances it is possible, by means of suitable contact brushes, to obtain from the two extremities of the magnet an induced current of such a magnitude as cannot be explained by the cutting of the rotating lines of force by the extremely short brushes employed. These currents can be explained if we suppose, as did Faraday at one time, that a rotating magnet cuts its own lines of force which remain fixed in space.

MR. CARL BARUS, in the current number of the *American Journal of Science*, describes a simple chronograph pendulum which is likely to be very useful to those who have no break-circuit chronometer or seconds clock at their disposal. It is a simple mechanism by which an ordinary seconds pendulum is both kept in motion and made to record its oscillations on one or more chronographs sharply. The heavy metallic bob of the pendulum is electrically connected with the knife-edge, and its top is surmounted by a soft iron armature, which is attracted during part of the swing by an electromagnet, and thus kept in motion. A longer and very much lighter pendulum, consisting of a flat bob suspended by two wires, is suspended by the side of the first, and swings in the same plane, but with a longer period. As the heavy pendulum approaches it, it touches a platinum spring projecting from the other bob, makes current for a moment, and works the chronograph, and at the same time sends the current through the electromagnet. The contact is quite momentary, as the spring causes the wire pendulum to be hurled off ballistically. On its return it is brought to rest, without rebounding, by a stop, against which it leans till the seconds pendulum returns. The bob of the light pendulum is made up of two small square parallel plates, between which the wires and the platinum strip are clutched by a single central screw. A band of platinum foil is wrapped round the heavy bob, in order to ensure reliable electric contact. The chronographs and the electromagnet are connected in parallel. The records show that the time of contact does not reach 0·1 sec. It is desirable to use electromagnets of high resistance to prevent exhausting the battery.

PART I. of vol. vii. of *Cohn's Beiträge* is taken up with a long paper, by Dr. W. Rothert, on Heliotropism. He finds that the heliotropic stimulus received on one part may be transmitted to another part of the same organ, or even to a different organ, and there give rise to heliotropic curvature. The transmission can only take place in a basipetal direction, and its rate is always small; in favourable cases 2 cm. per hour. Contrary to Darwin's views, he believes that the whole region which is capable of heliotropic curvature, is also heliotropically sensitive, although this sensitiveness is often unequally distributed in the same region. In all cases of this unequal distribution, it is a small region at the apex of the organ which is distinguished by a greater sensitiveness, whilst the rest exhibits this sensitiveness often in a far less degree. Further, the author investigated the effects of cutting off the apex of the cotyledon of seedlings of grasses, and found that this gives rise to two independent phenomena: a diminution in the rate of growth of the base, and a complete suspension of its heliotropic and geotropic sensitiveness. Both these effects are, however, only temporary. It was also unexpectedly found that these effects are not consequent on every injury done to the cotyledon, but that large cuts made either into the apex, or even two semi-sections made below the apex from opposite sides of the organ, and only 2 mm. apart, do not cause the diminution in the rate of growth, nor the suspension of heliotropic and geotropic sensitiveness, but that this is only effected by the complete section of the cotyledon.

MESSRS. W. WESLEY AND SON'S "Natural History and Scientific Book Circular," No. 122, contains a full classified list of important works on botany.

THE thirteenth monthly part of "The Royal Natural History" (Frederick Warne and Co.), being the first part of the third volume of the work, has been published.

THE Royal College of Physicians, Edinburgh, has just issued the fifth volume of Reports from their Laboratory, edited by Drs. J. Batty Tuke and D. Noël Paton. The volume presents the results of investigations carried out during the past two years.

THE ninth number of the handy and useful *Alembic Club Reprints* (Edinburgh: W. F. Clay) is devoted to Davy's papers on the property and nature of "muriatic acid" and "oxymuriatic acid," published in the *Philosophical Transactions* between 1809 and 1818. Our readers need hardly be reminded that though Gay-Lussac and Thenard were inclined to believe in the elementary nature of the latter, it was Davy who established the correctness of this view. This reprint of the eight communications to the Royal Society, on his experiments to demonstrate the elementary nature of chlorine, will be valued by students of historical chemistry.

WE have received No. 6 of *The Scientific Roll*, conducted by A. Ramsay, and dealing with the baric condition of the atmosphere. This publication is intended to be a summary of what is known of this subject from the works of various writers, so that anyone may make himself acquainted with what has been written without obtaining and reading the original books, some of which are now difficult of access. The present number contains notes taken from Prof. Kämtz' *Vorlesungen über Meteorologie*, published in 1840, and translated into English by Mr. C. V. Walker in 1845. In addition to retaining the original scales, the author reduces all values to what he terms the "baric unit," which is taken as equivalent to one million pounds weight on the square mile. Thus one inch of mercury at 60° F., and under the ordinary pressure of sea-level, corresponds to 2000 such baric units, and a millimetre under the same conditions to 78·74 baric units.

PROF. LOTHAR MEYER communicates to the *Berichte* a warning note concerning the dangerous nature of explosive mixtures of acetylene and oxygen. It is a well-known fact, frequently demonstrated upon chemical lecture-tables, that detonating mixtures of hydrogen and oxygen, or of marsh gas, ethylene, or carbon monoxide and oxygen, may be ignited in an open glass cylinder without danger provided the vessel is not narrowed at the neck, which would be likely to cause undue pressure. Prof. Meyer states that he has frequently performed the experiment with the above gaseous mixtures, employing a strong straight glass cylinder four centimetres wide and with very thick base, without ever having experienced an accident. Upon performing the experiment recently, however, with a mixture of acetylene and two and a half to three times its volume of oxygen, igniting the gas by approaching the mouth of the cylinder to a flame, the cylinder was blown to innumerable fragments in his hand, happily and almost miraculously without injuring him, although unprotected by a cloth, and the report of the explosion was so loud as to deafen for a time those in the neighbourhood. It has long been known that acetylene explodes with oxygen in closed vessels with great violence, frequently destroying an eudiometer, but this remarkable destruction of an open cylinder is a new evidence of its disruptive force. In the year 1884 Prof. Meyer, in conjunction with Prof. Seubert, showed that the detonating mixture of acetylene and oxygen ignites at a lower pressure than all other combustible gases, a pressure equal to thirty-two millimetres of mercury being sufficient to enable it to explode, while hydrogen and oxygen require a pressure of at least one hundred millimetres, and carbon monoxide and oxygen over two hundred millimetres. This, however, is not sufficient to account for the enormous pressure developed in an open cylinder. Moreover, it cannot be due to the more rapid rate of propagation of the explosion, for M. Berthelot and Prof. Dixon have independently found that the rapidity in the case of the acetylene detonating mixture is but slightly greater than in the mixtures of oxygen with ethylene or marsh gas, and much less than in the case of a mixture of hydrogen and oxygen. Prof. Meyer suggests that the smaller amount of hydrogen contained in acetylene than the other hydrocarbons, resulting in the production of less water vapour and relatively more carbon dioxide, together with the fact that the theoretical temperature of the combustion calculated from existing thermal data, is extremely high in the case of acetylene, may afford some explanation of the extraordinary energy developed during the explosion of the latter.

A PURE white di-sulphide of tin has been obtained by Dr. Schmidt in the laboratory of the Berlin University, which is further distinguished by the property of being readily soluble in ammonium carbonate. It may easily be prepared as follows: Metallic tin is first dissolved in hydrochloric acid, and the stannous chloride oxidised by digestion with nitric acid to stannic chloride, and the excess of acid largely removed by evaporation. After dilution with water the tin is precipitated as the ordinary yellow sulphide by sulphuretted hydrogen. The washed precipitate is next freed from traces of arsenic by solution in concentrated hydrochloric acid and reprecipitating the diluted and filtered solution with sulphuretted hydrogen. The well-washed yellow precipitate is then digested with a large excess of ammonium hydrate for some days at the ordinary temperature, when the whole of it eventually dissolves except small traces of the black sulphides of lead and bismuth. Upon diluting the clear ammoniacal solution and neutralising it with dilute sulphuric acid, an almost perfectly white precipitate is obtained. This precipitate dissolves at once almost completely in ammonium carbonate, and upon again neutralising with dilute sulphuric acid the disulphide precipitated is pure white. This new form of stannic sulphide is very voluminous, and it apparently owes its absence of colour and greater bulk to the fact that stannic sulphide here exists either in a different state of molecular aggregation or of hydration. It is significant that upon drying it becomes amber-yellow and loses its property of dissolving in ammonium carbonate.

THE additions to the Zoological Society's Gardens during the past week include a Lesser White-nosed Monkey (*Cercopithecus petaurista*), a Pel's Owl (*Scotopelia peli*), an Angolan Vulture (*Gypohierax angolensis*), a Black Kite (*Milvus migrans*), a Buzzard (*Buteo*, sp. inc.) from West Africa, presented by Mr. C. B. Mitford; two —— Baboons (*Cynocephalus*, sp. inc.) from East Africa, presented by Mr. Charles Palmer; a Chilian Sea Eagle (*Geranoaetus melanoleucus*) from South America, presented by the Rev. Fred L. Curne; two Bronze-winged Pigeons (*Phaps chalcoptera*) from Australia, presented by Mrs. Amy Jones; ten Surinam Toads (*Pipra americana*) from Surinam, presented by Mr. F. E. Blaauw; five Three-streaked Euprepes (*Euprepes trivittatus*) from South Africa, presented by Mr. J. E. Matcham: a Muscat Gazelle (*Gazella muscatensis*) from Muscat, an Echnida (*Echnida hystrix*) from New South Wales, deposited; four Lapwings (*Vanellus cristatus*), British, purchased.

OUR ASTRONOMICAL COLUMN.

OBSERVATIONS OF THE TRANSIT OF MERCURY.—Several French astronomers made preparations for observing the recent transit of Mercury across the sun, but the weather conditions on the other side of the Channel were just as unfavourable as they were here. The current *Comptes rendus* contains a brief note on the transit, by M. Trouvelot. This observer saw Mercury projected upon the sun at 4h. 12m. The planet was sharply defined, and appeared as a circular, intensely black, spot on the luminous background of the sun. In spite of careful observation, M. Trouvelot was unable to detect any trace of a luminous ring such as he observed round the planet during the transit of 1878. The unfavourable conditions of observation, however, are sufficient to explain the absence of the phenomenon.

Dr. Janssen also contributes a note on the transit of Mercury to *Comptes rendus*. He intended to look particularly for the "black-drop" observed during the transit of Venus in 1874, but clouds prevented the observation.

EPHEMERIS OF ENCKE'S COMET.—The following positions for Encke's Comet during this year are from an ephemeris given by Dr. O. Backlund in the *Astronomische Nachrichten*, No. 3263. The comet will pass perihelion on February 4, 1895. In the year 1862, its perihelion passage occurred on February 6.

RECENT OBSERVATIONS OF JUPITER.—Prof. E. E. Barnard communicates to this month's *Astronomy aud Astro-Physics* an account of his recent observations of the great red spot and other markings on Jupiter. The following points with regard to these features are of interest to observers: "The surface of Jupiter is very strongly marked, during this opposition, by two broad reddish belts, one on each side of the equator, and a broad white belt between them at the equator. The great red spot is fairly distinct in outline, though quite pale—a feeble red. The great bay in the south equatorial belt north of the red spot is still persistent and well marked." Prof. Barnard has observed a number of small black and white spots in Jupiter's northern hemisphere. Two of these objects, a black and a white spot, can easily be seen opposite the great red spot on the planet's disc. Prof. Barnard's measures indicate that the white spot will be in conjunction with the dark one about the middle of January next year, but as the two objects are not exactly on the same parallel, they will only graze in passing one another. The black spot appears to have about the same rotation period of the great red spot. Numerous white spots have been observed in Jupiter's southern hemisphere. A few dusky markings have also been seen on the great white equatorial belt.

THE NEW CYPRESS OF NYASALAND.

IN the most easterly corner of the British Protectorate of Nyasaland, immediately south of Lake Shirwa (between 35° and 36° E. lat, and a little north of 16° S. lat.), lies the large isolated mountain-mass of Milanji. From the plains which surround it the land rises gradually to a height of about 3000 feet, and forms the lower spurs of the mountain. Above these outliers the mountain is carried up another 3000 feet in abrupt elevations, only broken in places where the larger streams flow down. This rampart of cliffs borders the upper plateau of Milanji, which is elevated about 6000 feet above the sea-level, and is of considerable extent, though split up into various portions by ravines and precipices. In the centre of the plateau peaks rise to a further height of 3500 feet, thus giving Milanji a total elevation of nearly 10,000 feet above the sea-level.[1]

Mr. Alexander Whyte, the naturalist attached to the staff of Mr. H. H. Johnston, C.B., H.B.M. Commissioner and Consul-General, who usually resides at Zomba, made a botanical excursion to Milanji in 1892, and obtained a good series of the mountain-plants. An account of this collection, prepared by the officers of the Botanical Department in the British Museum, is given in a recently issued part of the Botanical *Transactions* of the Linnean Society.

Among the many plants new to science discovered by Mr. Whyte, and described in this memoir, one is of special interest, owing to its importance from an economic point of view.

In his exploration of the mountain, Mr. Whyte was much impressed with "a large cypress," which formed the most striking feature of the upper plateau. One prostrate trunk, and that by no means the largest seen, measured 140 feet in length, with a diameter of 5½ feet at six feet from the base, and had a clean, straight stem of ninety feet. In other cases long straggling branches are given off nearer the base, as shown in the accompanying figure, prepared by Mr. Worthington Smith from a photograph, and kindly lent to us by the Linnean Society. The timber is of a pale reddish colour, of excellent quality, and easily worked. The bark on the old trees is of great thickness, consisting of layers which are annually shed and renewed. The foliage recalls that of the juniper, while the fruits or cones, which are crowded from four to six together on short lateral shoots, are about three-quarters of an inch long, and from that to one inch wide when open. They consist of four thick woody scales, united below, spreading above, and bearing at their bases on the internal surface a number of small winged seeds.

Examination of the specimens sent home has shown that we are here dealing with a new species of *Widdringtonia*, a small genus of conifers allied to the cypress and juniper. Mr. Whyte's discovery has considerable scientific interest, from the fact that it extends the geographical range of the genus, hitherto known only from South Africa, Madagascar and Mauritius, into tropical Africa; and his name has been fittingly associated with the plant, which will henceforth be known as *Widdringtonia whytei*.

The Milanji Cypress (*Widdringtonia whytei*).

Its nearest ally, *W. juniperoides*, is found in the Cederberg Mountains, Cape Colony, where, according to a note by Parlatore in De Candolle's *Prodromus* (vol. xvi. part 2, p. 442), it once formed large forests, but is now rare. The Milanji species is also threatened with extinction; in this case by the bush-fires, the devastating effects of which, Mr. Whyte says, it is deplorable to witness, and which reach even the lofty and almost inaccessible plateau. These fires, originating during the

[1] See "Routes and Districts in Southern Nyasaland," by Bertram L. Sclater, R.E., *Geograph. Journ.*, November 1893.

dry months of August and September in the villages on the lower slopes of the mountain, gradually creep up the precipitous cliffs from tuft to tuft of dried herbage till they gain the grassy table-lands, and raging over the plain eat their way along the edges of the remaining belts of forest; annually scorching, if not burning, the bark and timber of the outside trees, and killing outright the young seedlings. In exceptionally dry seasons even the damper gorges are invaded, and Mr. Whyte describes hundreds of giant trees lying prostrate and piled on each other in all stages of destruction. We are glad to learn that Mr. Johnston, under whose directions Mr. Whyte's exploration was made, has taken steps to prevent a recurrence of such disasters.

Widdringtonia whytei promises to be of great economic value from the excellent quality of its timber for building purposes and furniture. It is easily worked, and is moreover a tree of rapid growth, for Mr. Whyte tells us that in a plantation which he has formed near the residency at Zomba, three-year-old seedlings have already reached a height of ten feet.

Seeds of the new conifer, forwarded by Mr. Whyte, reached this country in 1893, and healthy seedlings have been raised in the Royal Gardens, Kew; in the Botanical Gardens, Edinburgh; in Messrs. Veitch's Nurseries; and in the Zoological Society's Gardens; so that we may hope to see this fine tree ultimately established in Europe.

The existence of a large cedar-like tree on Milanji was first discovered by the Rev. Robert Acland, of the Blantyre Mission, who visited the mountain in 1889 for the purpose of founding a Mission Station. In Mr. Buchanan's narrative of his journey along the southern frontier of Nyasaland (*Proc. R. Geogr. Soc.* 1891, p. 271) it will be found alluded to as "a species of pine-tree" existing in the ravines on the north-eastern slope. In the latter part of 1891, Dr. W. A. Scott and Mr. Henry Brown made the first ascent of Milanji, going up the southern face, and ascertained the existence of large forests of the so-called "pine" at an altitude of 6000 feet above sea-level. A month later Mr. Whyte succeeded in ascending to the trees, and, as already stated, obtained the first specimens which reached this country, and enabled the tree to be classified and described.

When Fort Lister was founded in 1893, the cedar forests were found to come down to a much lower altitude on the north-east slopes of Mt. Milanji, and advantage was at once taken of this to procure a supply of the timber. It was cut up on the spot, and the planks carried to Zomba, where they have been employed for many purposes. When the residency at Zomba was re-roofed with iron this timber was used for the woodwork. There can be, therefore, no question about the value of this discovery.

SCHIAPARELLI ON MARS.

THE following extracts from a translation communicated to *Astronomy and Astro-Physics*, by Prof. W. H. Pickering, are of special interest at the present time, for they set forth Schiaparelli's observations of the planet Mars, and show his views on various Martian phenomena. The original article was contributed by this keen observer to *Natura ed Arte*.

THE POLAR CAPS.

Many of the first astronomers who studied Mars with the telescope, noted on the outline of its disc two brilliant white spots of rounded form and of variable size. In process of time it was observed that whilst the ordinary spots upon Mars were displaced rapidly in consequence of the planet's daily rotation, changing in a few hours both their position and their perspective, that the two white spots remained sensibly motionless at their posts. It was concluded rightly from this, that they must occupy the poles of rotation of the planet, or at least must be found very near to them. Consequently they were given the name of polar caps or spots. And not without reason is it conjectured, that these represent upon Mars an immense mass of snow and ice, similar to that which to-day prevents navigators from reaching the poles of the Earth. We are led to this conclusion not only by the analogy of aspect and of place, but also by another important observation.

As things stand, it is manifest, that if the white polar spots of Mars represent snow and ice, they should continue to decrease in size with the approach of summer in those places, and increase during the winter. Now this very fact is observed in the most evident manner. In the second half of the year 1892 the southern polar cap was in full view; during that interval, and especially in the months of July and August, its rapid diminution from week to week was very evident, even to those observing with common telescopes. This snow (for we may well call it so), which in the beginning reached as far as latitude 70°, and formed a cap of over 2000 kilometres (1200 miles) in diameter, progressively diminished, so that two or three months later little more of it remained than an area of perhaps 300 kilometres (180 miles), at the most, and still less was seen later in the last days of 1892.[1] In these months the southern hemisphere of Mars had its summer; the summer solstice occurring upon October 13. Correspondingly the mass of snow surrounding the northern pole should have increased; but this fact was not observable, since that pole was situated in the hemisphere of Mars which was opposite to that facing the Earth. The melting of the northern snow was seen in its turn in the years 1882, 1884, and 1886.

The southern snow, however, presents this peculiarity, that the centre of its irregularly rounded figure does not coincide exactly with the pole, but is situated at another point, which is nearly always the same, and is distant from the pole about 300 kilometres (180 miles) in the direction of the Mare Erythræum. From this we conclude that when the area of the snow is reduced to its smallest extent, that the south pole of Mars is uncovered; and therefore, perhaps, the problem of reaching it upon this planet is easier than upon the Earth. The southern snow is in the midst of a huge dark spot, which with its branches occupies nearly one-third of the whole surface of Mars, and is supposed to represent its principal ocean. Hence the analogy with our arctic and antarctic snows may be said to be complete, and especially so with the antarctic one.

The mass of the northern snow-cap of Mars is on the other hand centred almost exactly upon its pole. It is located in a region of yellow colour, which we are accustomed to consider as representing the continent of the planet. From this arises a singular phenomenon which has no analogy upon the Earth. At the melting of the snows, accumulated at that pole during the long night of ten months and more, the liquid mass produced in that operation is diffused around the circumference of the snowy region, converting a large zone of surrounding land into a temporary sea, and filling all the lower regions. This produces a gigantic inundation, which has led some observers to suppose the existence of another ocean in those parts, but which does not really exist in that place, at least as a permanent sea. We see then (the last opportunity was in 1884) the white spot of the snow surrounded by a dark zone, which follows its perimeter in its progressive diminution, upon a constantly diminishing circumference. The outer part of this zone branches out into dark lines, which occupy all the surrounding region, and seem to be distributory canals, by which the liquid mass may return to its natural position. This produces in these regions very extensive lakes, such as that designated upon the map by the name of *Lacus Hyperboreus*; the neighbouring interior sea called *Mare Acidalium* becomes more black, and more conspicuous. And it is to be remembered as a very probable thing, that the flowing of this melted snow is the cause which determines principally the hydrographic state of the planet, and the variations that are periodically observed in its aspect. Something similar would be seen upon the Earth, if one of our poles came to be located suddenly in the centre of Asia or of Africa. As things stand at present, we may find a miniature image of these conditions in the flooding that is observed in our streams at the melting of the Alpine snows.

Other white spots of a transitory character, and of a less regular arrangement, are formed in the southern hemisphere, upon the islands near the pole, and also in the opposite hemisphere, whitish regions appear at times surrounding the north pole, and reaching to 50° and 55° of latitude. They are perhaps transitory snows, similar to those which are observed in our latitudes. But also in the torrid zone of Mars are seen some very small white spots more or less persistent. Perhaps we may be permitted to account for these by the existence of a mountain capable of supporting extensive ice-fields. The existence of such a mountain has been supposed also by some recent observers, founded upon other facts.

MARTIAN METEOROLOGY.

As has been stated, the polar snows of Mars prove, in an incontrovertible manner, that this planet, like the Earth, is surrounded by an atmosphere capable of transporting vapour from one place to another. These snows are in fact precipitations of

[1] A note on the melting of the southern snow-cap this year appeared in the last number of NATURE (p. 64).

vapour, condensed by the cold, and carried with it successively. How carried with it, if not by atmospheric movement? The existence of an atmosphere charged with vapour has been confirmed also by spectroscopic observations, principally those of Vogel; according to which this atmosphere must be of a composition differing little from our own, and above all *very rich in aqueous vapour*. This is a fact of the highest importance, because from it we can rightly affirm with much probability, that to water, and to no other liquid is due the seas of Mars and its polar snows. When this conclusion is assured beyond all doubt, another one may be derived from it, of not less importance—that the temperature of the Arean climate, notwithstanding the greater distance of that planet from the Sun, is of the same order as the temperature of the terrestrial one. Because, if it were true, as has been supposed by some investigators, that the temperature of Mars was on the average very low (from 50° to 60° below zero!), it would not be possible for water vapour to be an important element in the atmosphere of that planet, nor could water be an important factor in its physical changes; but would give place to carbonic acid, or to some other liquid whose freezing point was much lower.

The elements of the meteorology of Mars seem then to have a close analogy to those of the Earth. But there are not lacking, as might be expected, causes of dissimilarity. From circumstances of the smallest moment, nature brings forth an infinite variety in its operations. Of the greatest influence must be the different arrangement of the seas and the continents upon Mars, and upon the Earth. We have already emphasised the fact of the extraordinary periodical flood, which at every revolution of Mars inundates the northern polar region at the melting of the snow. Let us now add that this inundation is spread out to a great distance by means of a network of canals, perhaps constituting the principal mechanism (if not the only one) by which water (and with its organic life) may be diffused over the arid surface of the planet. Because on Mars it rains very rarely, *or perhaps even, it does not rain at all.*

The atmosphere of Mars is nearly perpetually clear, and sufficiently transparent to permit one to recognise, at any moment whatever, the contours of the seas and continents, and more than that, even the minor configurations. Not indeed that vapours of a certain degree of opacity are lacking, but they offer very little impediment to the study of the topography of the planet. Here and there we see appear from time to time a few whitish spots, changing their position and their form, rarely extending over a very wide area. They frequent by preference a few regions, such as the islands of the *Mare Australe*, and on the continents, the regions designated on the map with the names of *Elysium* and *Tempe*. Their brilliancy generally diminishes and disappears at the meridian hour of the place, and is reinforced in the morning and evening, with very marked variations. It is possible that they may be layers of cloud, because the upper portions of terrestrial clouds, where they are illuminated by the Sun, appear white. But various observations lead us to think that we are dealing rather with a thin veil of fog, instead of a true nimbus cloud, carrying storms and rain. Indeed it may be merely a temporary condensation of vapour, under the form of dew or hoar-frost.

Accordingly, as far as we may be permitted to argue from the observed facts, the climate of Mars must resemble that of a clear day upon a high mountain. By day a very strong solar radiation hardly mitigated at all by mist or vapour, by night a copious radiation from the soil towards celestial space, and because of that a very marked refrigeration. Hence a climate of extremes, and great changes of temperature from day to night, and from one season to another. And as on the Earth at altitudes of 5000 and 6000 metres (17,000 to 20,000 feet), the vapour of the atmosphere is condensed only into the solid form, producing those whitish masses of suspended crystals, which we call cirrus clouds, so in the atmosphere of Mars, it would be rarely possible (or would even be impossible) to find collections of cloud capable of producing rain of any consequence. The variation of the temperature from one season to another would be notably increased by their long duration, and thus we can understand the great freezing and melting of the snow, which is renewed in turn at the poles at each complete revolution of the planet around the Sun.

TOPOGRAPHICAL TINTS.

In its general topography Mars does not present any analogy with the Earth. A third of its surface is occupied by the great *Mare Australe*, which is strewn with many islands, and the continents are cut up by gulfs and ramifications of various forms. To the general water system belongs an entire series of small internal seas, of which the Hadriacum and the Tyrrhenum communicate with it by wide mouths, whilst the Cimmerium, the Sirenum, and the Solis Lacus are connected with it only by means of narrow canals. We shall notice in the first four a parallel arrangement, which certainly is not accidental, as also not without reason is the corresponding position of the peninsulas of Ausonia, Hesperia, and Atlantis. The colour of the seas of Mars is generally brown, mixed with grey, but not always of equal intensity in all places, nor is it the same in the same place at all times. From an absolute black it may descend to a light grey, or to an ash colour. Such a diversity of colours may have its origin in various causes, and is not without analogy also upon the Earth, where it is noted that the seas of the warm zone are usually much darker than those nearer the pole. The water of the Baltic, for example, has a light, muddy colour, that is not observed in the Mediterranean. And thus in the seas of Mars we see the colour become darker when the sun approaches their zenith, and summer begins to rule in that region.

All of the remainder of the planet, as far as the north pole, is occupied by the mass of the continents, in which, save in a few areas of relatively small extent, an orange colour predominates, which sometimes reaches a dark red tint, and in others descends to yellow and white. The variety in this colouring is in part of meteorological origin, in part it may depend on the diverse nature of the soil, but upon its real cause it is not as yet possible to frame any very well-grounded hypothesis. Some have thought to attribute this colouring to the atmosphere of Mars, through which the surface of the planet might be seen coloured, as any terrestrial object becomes red, when seen through red glass. But many facts are opposed to this idea, among others, that the polar snows appear always of the purest white, although the rays of light derived from them traverse twice the atmosphere of Mars under great obliquity. We must then conclude that the Arean continents appear red and yellow, because they are so in fact.

Besides these dark and light regions, which we have described as seas and continents, and of the nature of which there is at present scarcely left any room for doubt, some others exist, truly of small extent, of an amphibious nature, which sometimes appear yellowish like the continents, and are sometimes clothed in brown (even black in certain cases), and assume the appearance of seas, whilst in other cases their colour is intermediate in tint, and leaves us in doubt to which class of regions they may belong. Thus, all the islands scattered through the Mare Australe and the Mare Erythræum belong to this category, so too the long peninsula called Deucalionis Regio and Pyrrhæ Regio, and in the vicinity of the Mare Acidalium the regions designated by the names of Baltia and Nerigos. The most natural idea, and the one to which we should be led by analogy, is to suppose these regions to represent huge swamps, in which the variation in depth of the water produces the diversity of colours.

Not without reason, then, have we hitherto attributed to the dark spots of Mars the part of seas, and that of continents to the reddish areas which occupy nearly two-thirds of all the planet, and we shall find later other reasons which confirm this method of reasoning. The continents form in the northern hemisphere a nearly continuous mass, the only important exception being the great lake called the Mare Acidalium, of which the extent may vary according to the time, and which is connected in some way with the inundations which we have said were produced by the melting of the snow surrounding the north pole. To the system of the Mare Acidalium undoubtedly belong the temporary lake called Lacus Hyperboreus and the Lacus Niliacus. This last is ordinarily separated from the Mare Acidalium by means of an isthmus or regular dam, of which the continuity was only seen to be broken once for a short time in 1888. Other smaller dark spots are found here and there in the continental area, which we may designate as lakes, but they are certainly not permanent lakes like ours, but are variable in appearance and size according to the seasons, to the point of wholly disappearing under certain circumstances. Ismenius Lacus, Lunæ Lacus, Trivium Charontis and Propontis are the most conspicuous and durable ones. There are also smaller ones, such as Lacus Mœris and Fons Juventæ, which at their maximum size do not exceed 100 to 150 kilometres (60 to 90 miles) in diameter, and are among the most difficult objects upon the planet.

THE CANALS OR CHANNELS.

All the vast extent of the continents is furrowed upon every side by a network of numerous lines or fine stripes of a more or less pronounced dark colour, whose aspect is very variable. These traverse the planet for long distances in regular lines, that do not at all resemble the winding courses of our streams. Some of the shorter ones do not reach 500 kilometres (300 miles), others on the other hand extend for many thousands, occupying a quarter or sometimes even a third of a circumference of the planet. Some of these are very easy to see, especially that one which is near the extreme left-hand limit of our map, and is designated by the name of Nilosyrtis. Others in turn are extremely difficult, and resemble the finest thread of spider's web drawn across the disc. They are subject also to great variations in their breadth, which may reach 200 or even 300 kilometres (120 to 180 miles) for the Nilosyrtis, whilst some are scarcely 30 kilometres (18 miles) broad.

These lines or stripes are the famous canals of Mars, of which so much has been said. As far as we have been able to observe them hitherto, they are certainly fixed configurations upon the planet. The Nilosyrtis has been seen in that place for nearly one hundred years, and some of the others for at least thirty years. Their length and arrangement are constant, or vary only between very narrow limits. Each of them always begins and ends between the same regions. But their appearance and their degree of visibility vary greatly, for all of them, from one opposition to another, and even from one week to another, and these variations do not take place simultaneously and according to the same laws for all, but in most cases happen apparently capriciously, or at least according to laws not sufficiently simple for us to be able to unravel. Often one or more become indistinct, or even wholly invisible, whilst others in their vicinity increase to the point of becoming conspicuous even in telescopes of moderate power.

Every canal[1] (for now we shall so call them) opens at its ends, either into a sea, or into a lake, or into another canal, or else into the intersection of several other canals. None of them have yet been seen cut off in the middle of the continent, remaining without beginning or without end. This fact is of the highest importance. The canals may intersect among themselves at all possible angles, but by preference they converge towards the small spots to which we have given the name of lakes. For example, seven are seen to converge in Lacus Phoenicis, eight in Trivium Charontis, six in Lunæ Lacus, and six in Ismenius Lacus.

The normal appearance of a canal is that of a nearly uniform stripe, black, or at least of a dark colour, similar to that of the seas, in which the regularity of its general course does not exclude small variations in its breadth, and small sinuosities in its two sides. Often it happens that such a dark line opening out upon the sea is enlarged into the form of a trumpet, forming a huge bay, similar to the estuaries of certain terrestrial streams. The Margaritifer Sinus, the Aonius Sinus, the Auroræ Sinus, and the two horns of the Sabæus Sinus are thus formed, at the mouths of one or more canals, opening into the Mare Erythræum or into the Mare Australe. The largest example of such a gulf is the Syrtis Major, formed by the vast mouth of the Nilosyrtis, so called. This gulf is not less than 1800 kilometres (1100 miles) in breadth, and attains nearly the same depth in a longitudinal direction. Its surface is little less than that of the Bay of Bengal. In this case we see clearly the dark surface of the sea continued without apparent interruption into that of the canal. Inasmuch as the surfaces called seas are truly a liquid expanse, we cannot doubt that the canals are a simple prolongation of them, crossing the yellow areas or continents.

Of the remainder, that the lines called canals are truly great furrows or depressions in the surface of the planet, destined for the passage of the liquid mass, and constituting for it a true hydrographic system, is demonstrated by the phenomena which are observed during the melting of the northern snows. We have already remarked that at the time of melting they appeared surrounded by a dark zone, forming a species of temporary sea. At that time the canals of the surrounding region become blacker and wider, increasing to the point of converting, at a certain time, all of the yellow region comprised between the edge of the snow and the parallel of 60° north latitude, into numerous islands of small extent. Such a state of things does not cease, until the snow, reduced to its minimum area, ceases to melt. Then the breadth of the canals diminishes, the temporary sea disappears, and the yellow region again returns to its former area. The different phases of these vast phenomena are renewed at each return of the seasons, and we have been able to observe them in all their particulars very easily during the oppositions of 1882, 1884, and 1886, when the planet presented its northern pole to terrestrial spectators. The most natural and the most simple interpretation is that to which we have referred, of a great inundation produced by the melting of the snows—it is entirely logical, and is sustained by evident analogy with terrestrial phenomena. We conclude, therefore, that the canals are such in fact, and not only in name. The network formed by these was probably determined in its origin in the geological state of the planet, and has come to be slowly elaborated in the course of centuries. It is not necessary to suppose them the work of intelligent beings, and notwithstanding the almost geometrical appearance of all of their system, we are now inclined to believe them to be produced by the evolution of the planet, just as on the Earth we have the English Channel and the Channel of Mozambique.

THE GEMINATION OF THE CANALS.

The most surprising phenomenon pertaining to the canals of Mars is their gemination, which seems to be produced principally in the months which precede, and in those which follow the great northern inundation, at about the times of the equinoxes. In consequence of a rapid process, which certainly lasts at most a few days, or even perhaps only a few hours, and of which it has not yet been possible to determine the particulars with certainty, a given canal changes its appearance, and is found transformed through all its length, into two lines or uniform stripes, more or less parallel to one another, and which run straight and equal with the exact geometrical precision of the two rails of a railroad. But this exact course is the only point of resemblance with the rails, because in dimensions there is no comparison possible, as it is easy to imagine. The two lines follow very nearly the direction of the original canal, and end in the place where it ended. One of these is often superposed as exactly as possible upon the former line, the other being drawn anew, but in this case the original line loses all the small irregularities and curvature that it may have originally possessed. But it also happens that both the lines may occupy opposite sides of the former canal, and be located upon entirely new ground. The distance between the two lines differs in different geminations, and varies from 600 kilometres (360 miles) and more, down to the smallest limit at which two lines may appear separated in large visual telescopes—less than an interval of 50 kilometres (30 miles). The breadth of the stripes themselves may range from the limit of visibility, which we may suppose to be 30 kilometres (18 miles), up to more than 100 kilometres (60 miles). The colour of the two lines varies from black to a light red, which can hardly be distinguished from the general yellow background of the continental surface. The space between is for the most part yellow, but in many cases appears whitish. The gemination is not necessarily confined only to the canals, but tends to be produced also in the lakes. Often one of these is seen transformed into two short, broad, dark lines parallel to one another, and traversed by a yellow line. In these cases the gemination is naturally short, and does not exceed the limits of the original lake.

The gemination is not shown by all at the same time, but when the season is at hand, it begins to be produced here and there, in an isolated, irregular manner, or at least without any easily recognisable order. In many canals (such as the Nilosyrtis for example) the gemination is lacking entirely, or is scarcely visible. After having lasted for some months, the markings fade out gradually and disappear until another season equally favourable for their formation. Thus it happens that in certain other seasons (especially near the southern solstice of the planet) that few are seen, or even none at all. In different oppositions the gemination of the same canal may present different appearances as to width, intensity and arrangement of the two stripes, also in some cases the direction of the lines may vary, although by the smallest quantity, but still deviating by a small amount from the canal with which they are directly associated. From this important fact it is immediately understood that the gemination cannot be a fixed formation upon the surface of Mars, and of a geographical character like the canals.

The observation of the geminations is one of the greatest difficulty, and can only be made by an eye well practised in

[1] The correct translation of the Italian word *canale*, used with reference to the streaks on Mars, is channel or strait, and not canal.

such work, added to a telescope of accurate construction and of great power. This explains why it is that it was not seen before 1882. In the ten years that have transpired since that time, it has been seen and described at eight or ten observatories. Nevertheless, some still deny that these phenomena are real, and tax with illusion (or even imposture) those who declare that they have observed it.

EXPLANATIONS OF THE GEMINATION OF CANALS.

Having regard then to the principle that in the explanation of natural phenomena, it is universally agreed to begin with the simplest suppositions, the first hypotheses on the nature and cause of the geminations have for the most part put in operation only the laws of inorganic nature. Thus the gemination is supposed to be due either to the effects of light in the atmosphere of Mars, or to optical illusions produced by vapours in various manners, or to glacial phenomena of a perpetual winter, to which it is known all the planets will be condemned, or to double cracks in its surface, or to single cracks of which the images are doubled by the effect of smoke issuing in long lines and blown laterally by the wind. The examination of these ingenious suppositions leads us to conclude that none of them seem to correspond entirely with the observed facts, either in whole or in part. Some of these hypotheses would not have been proposed had their authors been able to examine the geminations with their own eyes.

It is far easier to explain the gemination if we are willing to introduce the forces pertaining to organic nature. Here the field of plausible supposition is immense, being capable of making an infinite number of combinations capable of satisfying the appearances even with the smallest and simplest means. Changes of vegetation over a vast area, and the production of animals, also very small, but in enormous multitudes, may well be rendered visible at such a distance. An observer placed in the moon would be able to see such an appearance at the times in which agricultural operations are carried out upon one vast plain—the seed-time and the gathering of the harvest. In such a manner also would the flowers of the plants of the great steppes of Europe and Asia be rendered visible at the distance of Mars—by a variety of colouring. A similar system of operations produced in that planet may thus certainly be rendered visible to us. But how difficult for the Lunarians and Areans to be able to imagine the true causes of such changes of appearance, without having first at least some superficial knowledge of terrestrial nature! So also for us, who know so little of the physical state of Mars, and nothing of its organic world, the great liberty of possible supposition renders arbitrary all explanations of this sort, and constitutes the gravest obstacle to the acquisition of well-founded notions. All that we may hope is that with time the uncertainty of the problem will gradually diminish, demonstrating, if not what the geminations are, at least what they cannot be. We may also confide a little in what Galileo called "the courtesy of nature," thanks to which, sometimes from an unexpected source, a ray of light will illuminate an investigation at first believed inaccessible to our speculations, and of which we have a beautiful example in celestial chemistry. Let us therefore hope and study.

EARLY BRITISH RACES.[1]

II.

IN continental caves human skeletons of this period have been found; of these, perhaps, the best known is the famous Neanderthal one, from a cave near Düsseldorf. Upon this skeleton alone it would not have been prudent to have based the characters of Palæolithic cave men, because the circumstances under which it was found have given rise to some doubt as to its being of this age, and it is by some considered to belong to the next period which we have to deal with. When it is taken in conjunction with others presenting similar characters, regarding which there is no doubt as to the age to which they belong, the evidence it affords is considerably strengthened. The find of two skeletons at Spey (in Belgium) in 1886, has been most important, both in advancing our knowledge and confirming the characters ascribed to this race from various less complete specimens. The cranium of the Neanderthal skeleton, though very imperfect, is long and proportionately narrow in form, having a cephalic index of 72, the glabella, brow ridges, and external orbital processes are enormously developed, the forehead is remarkably flattened, the occiput is prominent, and the elevation of the whole vault is extremely low. The skulls of both the Spey skeletons are also long and narrow, one having a cephalic index of 70, and the other of 74·6; the superciliary ridges and also the glabella are very prominent; the frontal sinuses are large, the external orbital processes are thick and projecting, the ridges on the frontal, parietal, and temporal bones for muscular attachments are strongly developed; the occiput is prominent with a well-marked "torus" at the junction of the curved muscular ridges, which are also large; the cranial vault is low and flattened from above downwards, and presents an antero-posterior curve very similar to the outline of the side of an ellipse. The malar bones have thick and broad orbital processes, the orbital cavities are deep, and the orbital breadth is but slightly inferior to the width; the zygomatic arches are large. The size of the lower molar teeth increases from before backwards, the first molar being the smallest, and the wisdom or last molar the largest. The lower jaw shows no prominence of the chin; indeed, it recedes somewhat from the alveolar border downwards, and has a symphesial angle of 111°. It is thus a counterpart of the Naulette mandible, which presents similar characters, both as regards the molars and symphesial angle. The stature of the Neanderthal skeleton, estimated from the length of the femur, is 1·604 metres (5 ft. 3 in.), and from the humerus 2 cm. less; that of the Spey skeleton (there being only one of these in which the long bones could be measured), estimated from the femur and tibia, is 1·504 metres (4 ft. 11½ in.), and from the femur alone, 1·540 metres (5 ft. 0⅝ in.). The stature of the Naulette skeleton, that of a woman, estimated from the ulna, is 1·433 metres (4 ft. 4½ in.), and shows that she also was very short.

The long bones of both upper and lower limbs of the Neanderthal skeleton are characterised by their unusual thickness, and the great development of the elevations and depressions for the attachment of muscles, the articular ends of the femur are also of larger size than usual. The femur of the Spey skeleton is more arched forward than usual, it is somewhat flattened from side to side in section, and the articular ends are of large size, especially the lower, in which there is enormous antero-posterior development of the articular surface of the condyles. The tibia is actually and proportionately very short, flattened laterally, and therefore platycnemic. The bones generally are remarkable for their stoutness, and indicate that the muscles attached to them were large and powerful, especially those of the lower limb. In respect to the platycnemism of the tibia, the Spey skeleton corresponds to the Langerie Basse and Madelaine bones from the Perigord Caves, and confirms in a very positive manner the evidence of their surroundings and relicts that Palæolithic people were sons of the chase, as it is connected with the development of the tibialis posticus muscle, and not a race character.

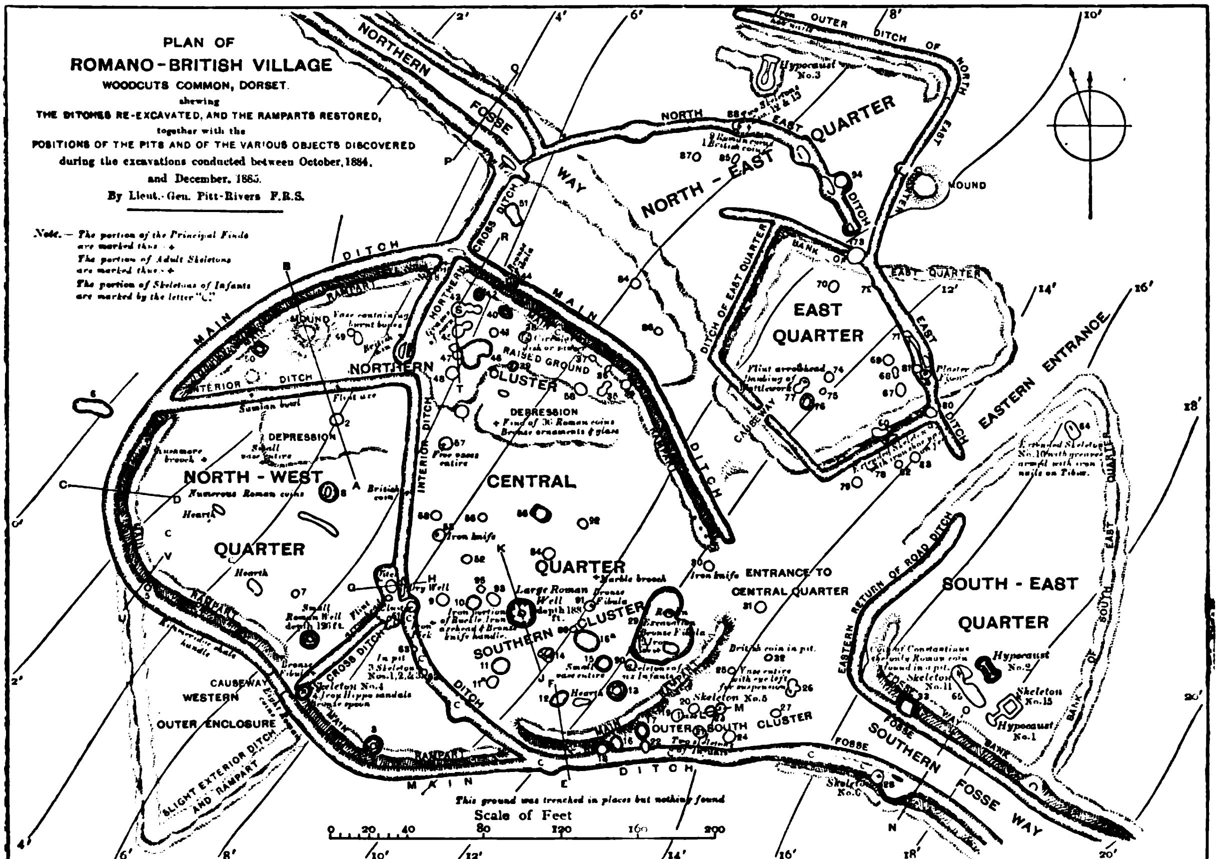
Portions of skulls and skeletons found in various parts of the continent, associated with Palæolithic implements and animal remains of late Pleistocene times, support the peculiar race characters of the specimens just described. The osteological remains of Palæolithic age now in hand from different parts of the continent seem to me to afford sufficient evidence of the existence, both in drift and in cave deposits, of a race of men possessing physical characters quite distinct from those of the Neolithic period, which we will next consider. The assertions which have been made at various times with respect to individual specimens being more or less pathological, will, to my mind, not hold good when we find specimen after specimen from the same deposits showing similar characters. It may not be possible, in some cases, to establish the fact that the specimen cannot have been deposited at a later period in the stratum in which it is found, but a careful examination of each specimen, such, for example, as Prof. Topinard has made of the mandible from Naulette, shows anatomical conditions which, not in one respect but in several, indicate as distinctly as his implements the progress of man's evolution, and preclude the idea of this type being a variety of the Neolithic people. The specimens of Palæolithic man seem to me to show identity of race, whether they have been found in the river-drift or in the Palæolithic stratum of caves. The idea of Prof. Boyd Dawkins, that the implements found in the river-drifts and later Palæolithic deposits of caves, give evidence of there being two Palæolithic races, is not supported by the osteological remains yet to hand. From extensive examination of ancient British skeletons,

[1] Continued from p. 70.

I do not consider that there is any evidence of the existence of the direct descendants of Palæolithic man among the osteological remains of Neolithic or subsequent date in Britain. Here he seems to be as extinct as many of his contemporary animals of the late Pleistocene period; this may not be the case with respect to his existence in other parts of Europe. Whether he has still representatives in America, as surmised by Prof. Boyd Dawkins and some American anthropologists, is outside the scope of the present lecture.

The next period at which we find remains of man in Britain is separated from the previous one by a space of time measurable only by the changes occurring in the interval. Great Britain and Ireland had once more become islands almost of the same dimensions as at the present day, with a moister and more continental climate—hotter in summer and colder in winter—abundant forests extending as far as the extreme north of Scotland, and numerous morasses and peat bogs. Not less significant was the advance in civilisation man had made since Palæolithic times, as we now find him dwelling in fixed habitations, with a knowledge of the arts and agriculture, with domestic animals, and with stone implements of a much more developed character, as he had now learned to smooth them by grinding and polishing.

These Neolithic people, as they are called, lived in camps, surrounded by ditches and ramparts, on the tops or sides of hills, or in suitable valleys. The camps were intersected with numerous drains or ditches, which would show that the climate was moist. Inside the camps they hollowed out pits, in or round which they dwelt. Excellent examples of the encampments or villages of the same Neolithic people, but of a much later date, have been discovered and described by General Pitt-Rivers in his excavations near Rushmore, from the main outlines of which some idea may be formed of what their earlier dwelling-places were probably like (Fig. 16). From these camps have been obtained spindle whorls and bone combs toothed at one end, showing that they were acquainted with the arts of spinning and weaving, bone needles, fragments of coarse pottery, made by hand and not turned on the wheel, either plain or ornamented with simple lines or dots, bones of the roe, red deer, dog, goat, short-horned ox, horse, pig, &c., and fish, but no trace of metal is found. Of all their implements the stone axe is perhaps the most important. Flints used for implement-making were now often quarried from below the soil, with antlers of deer as picks. The implements were distributed over districts far removed from where they were made, probably by barter, Jadite or Nephrite implements having been found in Britain, which Mr. Rudler has shown may have been obtained from Switzerland, Silesia, or Styria. They possessed canoes formed out of the trunks of trees, in which they probably reached this country from the continent.



Walker & Boutall sc.

FIG. 16.

They buried their dead in caves, which had been used a dwellings, in their camps, and in chambered and unchambered barrows. The most characteristic British barrows of this period are of long oval shape, and often of large size, but Neolithic interments are also found in circular barrows. The dead were buried in a contracted or crouched position, and with them, stone and bone implements of various kinds, and pottery, which would seem to show that these articles were intended for the use of the dead or their spirits. Relics of art in the form of carvings are seldom found, and are very inferior to those of late Palæolithic times.

Osteological remains of the Neolithic people are distributed all over Britain, from the south of England to the extreme north of Scotland. They are most numerous in the south-west of England, especially in Wilts and Gloucestershire, the part of the country occupied by the Drobuni, or Silures, at the beginning of the historic period. They have been found in considerable numbers in Yorkshire, Derbyshire, and Stafford. Huxley and Wilson have described the same race from horned cairns in Caithness, and from other places of Scotland. I have described them from Wiltshire, Yorkshire, Middlesex, and from Orkney.

There is some doubt of their having been found yet at an early period in Ireland, as Prof. Macalister informs me that he has not recognised them in Ireland, where there are no long barrows. Sir William Wild, on the other hand, recognised Neolithic skulls from Somersetshire as identical with certain ancient Irish skulls. Any skulls from Ireland I have seen, which have shown characters similar to the Neolithic skulls from England, are of later date, but Huxley describes them from chambered tombs, peat mosses, and river deposits of Ireland. I think we may conclude, as regards Ireland, that although it is doubtful whether the Neolithic people were there at as early a date as in Britain, they were certainly there later.

The characters of the skeletons are well marked. The skull is large and well formed, the calvaria is long and proportionally narrow, having a cephalic index of about 70, and of oval shape. The superciliary ridges and glabella are moderately or even feebly developed, the forehead is well formed, narrow, and curves gracefully to the occiput, which is full and rounded. The upper margins of the orbits are thin, and the malar bones are never prominent; the profile of the face is vertical, and there is no tendency to prognathism; the chin is prominent, the symphesial angle is from 70° to 80°; the length of the face from the root of the nose is comparatively short, but as a whole the face is oval in form; the jaws are small and fine, the teeth are of medium size, and generally in a good state of preservation, not much worn down. The last molar is always the smallest tooth of that series. The facial characters are mild, and without exaggerated development in any one direction; the same may be said of the calvaria generally. The age of the persons to whom they belong averages, according to Thurnam, forty-five years, which would seem to indicate that the duration of life was rather short at that time.

The stature of the Neolithic people is short. From Dr. Thurnam's measurements of the femora of twenty-five skeletons, it averages 1·674 m. (5ft. 6½in.) by Rollet's formula; but from my own observations of other specimens which have passed through my hands, I am inclined to consider this as too high an average. In their general characters the bones are slender, often with a well-marked *linea aspera* on the femur and platycnemic tibia, which would show that the Neolithic people led an active life, probably as hunters. Dr. Thurnam has noted that sometimes two or more of the cervical or dorsal vertebræ have a tendency to anchylosis, but I cannot say I have ever seen this.

On the continent of Europe remains of the Neolithic people are found chiefly in caves, and show much the same state of culture and physical features as just described, for instance the well-known Cro-Magnon race; but the sequence of their existence there is not so well defined as in Britain, where they held apparently undisputed possession of the country for a considerable period. Indeed, it is only lately that continental anthropologists have admitted their priority to that of people presenting the character of the next race we will have to deal with.

From the evidence to hand, it seems probable that the Neolithic people occupied the whole of the west of Europe at one time; and I agree with several observers in considering that they are to be identified with the old Iberian race, of which the Basque may be considered a remnant. There is certainly a strong similarity between Basque skulls and those of the Neolithic people of Britain.

Unlike Palæolithic man the Neolithic people have never become extinct in Britain, and their descendants exist to the present time. It is true that subsequent invaders drove them, in many instances, to particular parts of the country, as early history and the excavations of General Pitt-Rivers and others show; but skeletons from ancient tombs indicate that they also mixed with their conquerors.

The next people to appear upon the scene, previous to the dawn of history, are those who were in possession of the greater part of Britain at the time of the Roman invasion. They came into Britain from France and Belgium at a considerably earlier period, and subjugated or displaced the Neolithic race. These are the so-called Celts. Their advent is marked by the introduction of the use of metals into Britain, and they are associated with the Bronze age. From the custom they had of interring their dead, whom they chiefly cremated, in barrows of a circular shape, they are often known as the Round Barrow people. They show a marked advance in civilisation beyond that of Neolithic times, as they were agriculturists, and lived by tilling the soil; they manufactured weapons and ornaments of bronze, and richly decorated pottery; their flint implements also were of better make, as evidenced by their beautiful barbed arrow-heads. To this period belong many of the curious lake dwellings found all over Great Britain and Ireland, Picts houses of Scotland, and bee-hive houses of Ireland.

Their osteological remains show that the skull was large with strongly-developed superciliary ridges and glabella, the brow well formed and broad, the upper occipital region not projecting, the tuberosity being the most prominent. In general form the brain-case is broader and rounder than in the Neolithic race, the cephalic index centring round 81; they were, therefore, a distinctly brachycephalic people. The upper border of the orbit is thick, the malar bones are prominent and large. The jawbones are large, *macrognathous*, and likewise the teeth, which are often much ground down; the profile of the upper jaw is somewhat prominent, which gives a prognathous look to the skull; the chin is well formed. The face as a whole is of an angular lozenge form. The ridges for muscular attachments, both on the cranium and face, are well developed, and the expression is very rugged and savage-like. From the skull Thurnam estimated the average age of the persons interred in the round barrows was fifty-five years, while that of the long barrows was ten years less.

The stature of the Round Barrow race averages 1·747 metres (5 feet 9 inches), which is more than the mean stature of the population of the British Isles at the present day. The limb bones are large, with strongly-developed ridges and depressions for muscular attachments.

This race is everywhere to be found over Great Britain and Ireland, and although conquered by the Romans and subsequent invaders, forms a very important element of the population of the country down to the present day.

[I have to thank Prof. Boyd Dawkins for his kind permission to use woodcuts from his work on "Early Man in Britain," for the purpose of illustrating this publication of my lecture, and to General Pitt-Rivers for permitting the reproduction of a block from his plate in "Excavations near Rushmore," vol. ii. The lecture, as delivered at the Royal Institution, was illustrated by numerous lantern slides, which were not suitable for reproduction.]

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Statute relating to Research Degrees has been promulgated, and has given rise to some dissatisfaction among many of those who have hitherto warmly supported the scheme. The supervision of those who wish to qualify for a Research Degree is to be placed, according to the proposed Statute, in the hands of a Delegacy composed of the Vice-Chancellor and Proctors and twelve other members, to be nominated by the Vice-Chancellor and Proctors, the Hebdomadal Council, and the Members of Congregation This amounts to the creation of a new Delegacy similar in constitution and in powers to the existing Delegacy of non-collegiate students, and it is felt that it is a most unsuitable mode of supervising the work of men none of whom may be less than twenty-one years of age. It was thought that the supervision of the researchers should be vested in the Professorial body, and it is much to be hoped that the proposed Statute will be thrown out in Congregation, for it is nearly certain that no persons qualified for research would submit themselves to the supervision of such a heterogeneous body as the proposed Delegacy, and the scheme, of which so much is expected, would become a dead letter.

In a meeting of the Junior Scientific Club, held on Friday, November 16, Mr. P. Elford, of St. John's, exhibited a specimen of shale oil, and papers were read by Mr. F. Druce, of Magdalen College, on anticyclones and other types of atmospheric pressure, and by Mr. W. W. Fisher, of Corpus Christi College, on the Oxford water supply.

Mr. P. L. Sclater, F.R.S., has been elected an honorary Fellow of Corpus Christi College.

CAMBRIDGE.—Dr. Forsyth, F.R.S., has been appointed Chairman of the Examiners for Part II. of the Mathematical Tripos.

Mr. E. H. Hankin, Fellow of St. John's College, and Professor of Bacteriology at Agra, has been appointed to represent the University at the Indian Medical Congress to be held at Calcutta in December.

The following is the Syndicate appointed to consider a report on the question of special encouragement, by new degrees or otherwise, for post-graduate study and research in the University: The Vice-Chancellor, Dr. Maitland, Dr. D. Macalister, Dr. Jebb, Dr. Forsyth, F.R.S., Prof. Marshall, Prof. Gwatkin, Prof. Foster, F.R.S., Prof. Thomson, F.R.S., Mr. A. W. W. Dale, of Trinity Hall, and Mr. W. Bateson, F.R.S., of St. John's College.

A Grace authorising the Cavendish Laboratory Syndicate to obtain specifications and tenders for the proposed extension of the Laboratory, was offered to the Senate on November 22.

SCIENTIFIC SERIALS

American Journal of Science, November.—On variations and mutations, by W. B. Scott. The author discusses the problem of animal morphology in its various aspects, and the different lines along which a solution has been sought for. These are that of comparative anatomy, embryology, and palæontology, to which, since Bateson's work on the study of variation, a fourth has been joined. The author criticises in detail Bateson's method and its results, and comes to the conclusion that we can no longer assume as a fundamental and self-evident truth that individual variations are the material from which new species are constructed.—Resonance analysis of alternating currents, by M. J. Pupin. This analysis is performed by means of a "resonator circuit" consisting of an inertia coil, a rheostat and a condenser in shunt with an electrostatic voltmeter. The capacity of the condenser is gradually increased from zero upwards. Whenever a capacity has been reached, which with the self-induction of the resonator circuit produces resonance with one of the harmonics in the main circuit, then the resonant rise of potential produces a large deflection in the voltmeter. In this manner all the harmonics which are present in the current of the main circuit can be detected in a few minutes.—On some new methods of obtaining platinochlorides, and on the probable existence of a platinum subchloride, by M. Carey Lea. One of the new methods employs potassium acid sulphite, with a solution of which potassium platinic chloride is moderately heated. The reduction takes about ten to twelve hours, and is known to be complete when the solution has a pure red colour free from yellow. The second method is that with alkaline hypophosphites. If in obtaining potassium platinochloride with the aid of a hypophosphite in excess, the heat is continued after complete conversion to the red salt, the solution in a few minutes changes from red to dark brown. The substance which gives the solution this dark brown colour is very deliquescent, and cannot be crystallised. It cannot be completely separated from the other substances in solution. The author is led by its reactions to suspect that it is a subchloride of platinum, analogous to that of silver.

Journal of Anatomy and Physiology, October.—Dr. Gustav Mann, in a paper entitled "Histological Changes induced in Sympathetic, Motor and Sensory Nerve Cells by Functional Activity (preliminary note)," gives an account of experiments made by him to test the observations of Hodge and F. Vas. Dr. Mann's observations relate to the cervical sympathetic ganglia (which also formed the subject of F. Vas's investigations), the motor area of the cerebrum, and to the retina and optic centres of the brain. His results in part agree with those of Hodge, in part with those of Vas, but they also in other particulars go beyond both. He considers that he has placed beyond doubt, that: (1) During rest, several chromatic materials are stored up in the nerve cell, and that these materials are used up by it during the performance of its function. (2) Activity is accompanied by an increase in size of the cells, the nuclei, and the nucleoli of sympathetic, ordinary motor and sensory ganglionic cells. (3) Fatigue of the nerve cell is accompanied by shrivelling of the nucleus, and probably also of the cell, and by the formation of a diffuse chromatic material in the nucleus.

SOCIETIES AND ACADEMIES

LONDON.

Royal Society, November 15.—"On the Ascent of Sap." By Henry H. Dixon, Assistant to the Professor of Botany, Trinity College, Dublin, and Dr. J. Joly, F.R.S.

Strasburger's experiments have eliminated the direct action of living protoplasm from the problem of the ascent of sap, and have left only the tracheal tissue, as an organised structure, and the transpiration-activity of the leaf wherein to seek an explanation of the phenomenon. The authors investigate the capability of the leaf to transpire against excessive atmospheric pressures. In these experiments the leaf was found able to bring forward its water meniscuses against the highest pressures attained and freely transpire. Whether the draught upon the sap established at the leaf during transpiration be regarded as purely capillary or not, these experiments lead the authors to believe that it alone is quite inadequate to effect the elevation by direct tension of the sap in tall trees. Explanations of the lifting of the sap from other causes prove inadequate.

A reconsideration of the principal experiments of previous observers and some new experiments of the authors lead to the view that the ascent is principally in the lumen and not in the wall.

The explanation of how the tensile stress is transmitted in the ascending sap without rupture of the column of liquid is found in the stable condition of this liquid. The state of stability arises from two circumstances: the internal stability of a liquid when mechanically stretched, whether containing dissolved gases or not, and the additional stability conferred by the minutely subdivided structure of the conducting tissue, which renders the stressed liquid stable even in the presence of free gas.

By direct experiments upon water containing large quantities of dissolved air, the state of internal stability is investigated And, further, by sealing up in the vessels, in which the water to be put under tension is contained, chips of the wood of *Taxus baccata*, the authors find that their presence in no case gives rise to rupture of the stressed liquid, but that this occurs preferably anywhere else, and usually on the glass walls. The establishment of tensile stress is effected in the usual way, by cooling the completely filled vessel. A measurement possessing considerable accuracy afforded 7½ atmospheres as being attained in some of the experiments.

The second condition of stability arises directly from the property of the pit-membranes to oppose the passage of free gas, while they are freely permeable to the motion of a liquid. Hence a chance development of free gas is confined in effect to the minute dimensions of the compartment in which it is evolved, and this one lumen alone is rendered for the time being non-conducting. On the other hand, in the water-filled portion of the tracheal tissue, the closing membranes, occupying the median and least obstructive position, the motion of the stress sap is freely allowed. The structure of the conducting tissue is, in fact, a configuration conferring stability on a stressed liquid, in the presence (from various causes) of free gas. As neither free gas nor unwetted dust particles can ascend with the sap, the authors contend that the state of tensile stress necessary to their hypothesis is inevitably induced.

The energy relations of the leaf with its surroundings, on the assumption that evaporation at capillary water-surfaces is mainly responsible for the elevation of sap, may be illustrated by the well-known power of the water-filled porous pot to draw up mercury in a tube to which it is sealed. The authors describe an engine in which the energy entering in the form of heat at the capillary surfaces may be in part utilised to do mechanical work: a battery of twelve small porous pots, freely exposed to the air, keeping up the continuous rotation of a fly-wheel. Replacing the porous pots by a transpiring branch, this too maintains the wheel in rotation. This is, in fact, a vegetable engine. In short, the transpiration effects going on at the leaf are, in so far as they are the result of spontaneous evaporation and uninfluenced by other physiological phenomena, of the "sorting demon" class, in which the evaporating surface plays the part of a sink of thermal energy.

If the tensile stress in the sap is transmitted to the root, the authors suggest that this will establish in the capillaries of the root-surface meniscuses competent to condense water rapidly from the surrounding soil. They show by experiment the power possessed even by a root injured by lifting from the soil, of condensing water vapour from a damp atmosphere. Such a state of things may be illustrated by a system (which the authors realised) consisting of two porous pots connected by a tube and all filled with water; one, the "leaf," exposed to the air gives out vapour, the other, the "root," buried in damp earth supplies the demand of the "leaf," and an upward current in the connecting tube is established.

"Further Observations on the Organisation of the Fossil Plants of the Coal-Measures. Part ii. The Roots of *Calamites*." By Dr. W. C. Williamson, F.R.S., and Dr. D. H. Scott, F.R.S.

The conclusions at which the authors arrive are the following:—

(1) The fossils hitherto described under the name of *Astromyelon Williamsonis* are the adventitious roots of *Calamites*.

(2) Their structure is in all respects that characteristic of roots, as is proved by the centripetal primary wood, the alternating strands of primary wood and phloëm, the endogenous mode of branching, and the absence of nodes.

(3) The smallest specimens, with little or no medulla, represent the finest branches of the same roots, of which the large medullate forms are the relatively main axes.

Linnean Society, November 1.—Mr. C. B. Clarke, F.R.S., President, in the chair.—Mr. Alexander Whyte was admitted.—Messrs. H. and J. Groves exhibited an undescribed *Chara* from Westmeath, and made remarks upon its peculiar mode of growth.—Mr. J. O. Tepper exhibited photographs of a new and remarkable fungus from South Australia, *Laccocephalum basilapiloides*, which explained the formation of the peculiar stone-like nodules occasionally found when clearing scrub-land. These were found to be due to the agglutinating nature of the mycelium of this fungus, the grains being permanently cemented by lime and ferruginous oxides.—The Rev. G. Henslow made some remarks on a peculiar mode of propagation of *Oxalis cernua*, observed in Malta, and exhibited some views taken during his sojourn here.—Mr. Miller Christy exhibited a long piece of leaden pipe which had been gnawed through its entire length by rats, in a manner which showed that the object was not, as generally supposed, to get access to water.—Mr. H. M. Bernard exhibited some photographs of corals taken with the "Kodak" camera.—A series of that remarkable beetle *Golinthus giganteus*, from West Africa, was shown by Dr. Heath, and Mr. E. M. Holmes exhibited some plants from Japan.—On behalf of Mr. A. W. Waters, a paper was then read on Mediterranean and New Zealand Retipora and on a fenestrate bryozoan; and on behalf of Dr. J. Müller, a paper on certain lichens in the Kew Herbarium.

Zoological Society, November 6.—Sir W. H. Flower, K.C.B.,, F.R.S., President, in the chair.—The President read a letter addressed to him by the late Emin Pasha, containing a diary of ornithological observations made during the last part of his journey towards the Congo. This letter and journal had been taken from the Arabs on the Upper Congo by the officers of the Congo Free State, and forwarded to the President.—A communication from Mr. F. E. Blaauw, contained some remarks on the colour of the bill in a living specimen of *Cygnus americanus*.—A communication was read from Mr. R. Trimen, containing a reply to some remarks of Dr. A. G. Butler on his paper on the Manica Butterflies collected by Mr. Selous.—A communication was read from Dr. R. W. Shufeldt, containing a correction to his paper on the affinities of the *Steganopodes*, recently published in the Society's *Proceedings*.—Mr. O. Salvin, F.R.S., exhibited a pair of the newly described butterfly *Ornithoptera paradisea*, from the Finisterre Mountains, German New Guinea.—Mr. C. Davies Sherborn exhibited a copy of, and made remarks on the recently issued reprint of George Ord's "American Zoology."—Mr. G. A. Boulenger, F.R.S., exhibited a Gecko, forwarded to him by Mr. R. T. Lewis, which had been captured in winter (July), fully active, on the snow upon the highest portion of the Drakensberg Range, Natal. It belonged to a genus believed until 1888 to be characteristic of the Australian fauna, and differed from its nearest ally, *Œdura africana*, in the smaller and convex granules covering the head and in the rostral shield not entering the nostril. Mr. Boulenger proposed for it the name *Œdura nivaria*.—Mr. Martin Jacoby read descriptions of some new species of the genus *Œdionychis* and allied genera of Coleoptera.—Mr. W. G. Ridewood read a paper on the hyoid arch of *Ceratodus*. The author instituted a comparison between the ventral elements of the hyoid arch of *Ceratodus* and the basi- and hypo-hyal cartilages of the Elasmobranchii. The relations of the hyomandibular cartilage were dealt with in detail, and attention was called to the wide range of variation which this vestigial cartilage exhibits. Arguments were also adduced to show that there is no connection between the reduction of the hyomandibular in the Dipnoi and its adaptation as a secondary suspensorium in the hyostylic fishes.—Mr. G. A. Boulenger, F.R.S., read a third report on additions to the Batrachian Collection in the Natural History Museum, containing a list of the species, new or previously unrepresented, of which specimens had been added to the collection since 1890, and descriptions of some new species.—A communication was read from Mr. R. J. Lechmere Guppy, containing an account of some Foraminifera from the microzoic deposits of Trinidad.—A communication was read from Sir Walter L. Buller, containing remarks on a petrel lately described as new by Captain Hutton, under the name of *Œstrelata leucophrys*.

Geological Society, November 7.—Dr. Henry Woodward, F.R.S., President, in the chair.—Sir John Lubbock exhibited some interesting specimens from the valley of Lauterbrunnen at Murren. The rock forms part of the calcareous strata which stretch to the south-west to Leuk, and to the north-east to the celebrated gorges of the Aar. It has also a great thickness, and is coloured in the geological map of Switzerland as Malm, though some Swiss geologists have recently attributed it to the Trias. Notwithstanding the careful researches of the Swiss geologists no fossils, however, had yet been found in it. During one of the recent excursions of the International Geological Congress, Sir John Lubbock found a layer which is rich in fossils—amongst others *Nummulites Ramondi*, *Orbitoides disparesus* and *Orbitoides papyraceus*. The rock therefore is not Malm, but Eocene. The species have been verified by Prof. Rupert Jones. Sir John Lubbock showed the spot to Prof. Etheridge, who also exhibited some fossils from the same layer. The find will necessitate a substantial correction of the geological map, and is perhaps the more interesting because the specimens were found in a quarry by the roadside in the village of Murren, and actually between the two principal hotels.—Notes on some recent sections in the Malvern Hills, by Prof. A. H. Green, F.R.S. The sections described occur on the east side of the Herefordshire Beacon, and for convenience are named the Warren House Rocks. They are bedded, and have a general north-and-south strike. The great bulk of the rocks are hard, close-grained, and splintery, and are largely altered, and in many cases thickly veined with calcite. Details of their structure were given; and the author stated that he is inclined to regard them as a group of bedded acid lavas and tuffs, crossed by three bands of dolerite. What little balance of evidence there is seems to be in favour of the intrusive character of the dolerites. No true limestones have been found, and the only very calcareous rock seen is regarded as a rock belonging to the volcanic group which has been largely calcified. A discussion followed, in which Mr. Watts, Dr. Hicks, Mr. Rutley, and Mr. Harker took part.—The Denbighshire series of South Denbighshire, by Philip Lake. The area to which this paper chiefly referred is the south-western quarter of the Llangollen basin of Silurian rocks. The beds are there very little disturbed, and the sequence was readily made out. On comparison with other areas it was found that the succession is almost identical with that in the Long Mountain, in North Denbighshire, and in the Lake district. Prof. Hughes, Mr. Hopkinson, Dr. Hicks, Mr. Marr, and Mr. Watts made a few remarks upon the subject of the paper.—On some points in the geology of the Harlech area, by the Rev. J. F. Blake.

Entomological Society, November 7.—Colonel Charles Swinhoe, Vice-President, in the chair.—Colonel Swinhoe exhibited a female of *Papilio telearchus*, Hewitson, which he had received by the last mail from Cherra Punji. He said that this was the only known specimen of the female of this species, with the exception of one in Mr. L. de Nicéville's collection, which he had described in the *Journal* of the Bombay Natural History Society in 1893. He also exhibited a male of the same species for comparison.—Mr. C. G. Barrett exhibited abnormal forms of *Pararge megæra*, *P. ægeria*, *Melitea athalia*, *Chrysophanus phlœas*, *Charæas graminis*, *Lophopteryx camelina*, *Plusia gamma*, *Cucullia chamomillæ*, *Boarmia repandata*, var. *conversaria*, and other species, all collected by Major J. N. Still on Dartmoor, Devon. He also exhibited for Mr. Sydney Webb, of Dover, a long series of most remarkable varieties of *Arctia caja*, and *Arctia villica*.—Mr. Gervase F. Matthew, R.N., exhibited seven beautiful and striking varieties of *Arctia villica*, bred from larvæ obtained on the Essex coast, near Dovercourt, in March and April 1893 and 1894.—Herr Jacoby exhibited two specimens of *Blaps mucronatus*, with soft elytra, taken on a wall at Hampstead. The Rev. Canon Fowler and Mr. G. C. Champion made some remarks on the subject of the elytra of immature beetles.—Mr. H. Goss exhibited a specimen of *Periplaneta australasiæ*, received from Mr. C. E. Morris, of Preston, near Brighton. Mr. McLachlan said the species had been introduced into this country, but was now considered a British insect.—Mr. B. G. Rye exhibited specimens of the following rare or local species of Coleoptera, and gave the names of the localities in which they had been taken: *Cicindela germanica*, *Eumicrus rufus*, *Triarthron markeli*, *Mesium affine*, *Homaloplia ruricola*, *Anomala frischi*, var. *julii*, *Synaptus filiformis*, *Lixus paraplecticus*, *Balaninus cerasorum*, *Asemum striatum*, and *Zeugophora flavicollis*.—Mr. McLachlan exhibited for Mr. G. C. Bignell two new species of Ichneumonidæ, from Devonshire, viz. *Pimpla bridgmani*, Bign., a parasite on a spider, *Drassus lapidicolens*, Walck., and *Praon absinthii*, Bign., a parasite on *Siphonophora absinthii*, Linné.—Mr. C. O. Waterhouse stated that the Acridium received from Captain Montgomery, and exhibited by Mr. Goss at the last meeting, was *Acridium septemfasciatum*, and he exhibited the species with the wings extended.—Mr. Ridley exhibited a species of a scale insect (? *Lecanium*) found on a nutmeg tree in Malacca, and made some remarks on *Formica smaragdina*,, which makes its nest on the trees, joining the leaves together by a thin thread of silk at the ends. The first step in making the nest is for several ants to bend the leaves together and hold on with their hind legs, and one of their number after some time runs up with a larva, and irritating it with its antennæ, makes it produce a thread with which the leaves are joined; when one larva is exhausted a second is fetched, and the process is repeated.—Mr. Waterhouse read a paper entitled "Some remarks on the Antennæ of Insects." A discussion followed, in which Messrs. Champion, Jacoby, McLachlan, and Gahan took part.

Mathematical Society, November 8.—Mr. A. B. Kempe, F.R.S., President, in the chair.—At this meeting, which was the first held since the incorporation of the Society, the by-laws, which had been drawn up by the council, were passed unanimously. The ballot was then taken, and the gentlemen whose names were published in NATURE (November 1, No. 1305, p. 19) were declared duly elected to form the new council and officers. The new President (Major MacMahon, F.R.S.) having taken the chair, Mr. Kempe read his address, the title of which was "Mathematics." Other communications made were—a generalised form of the hypergeometric series, and the differential equation which is satisfied by the series, F. H. Jackson; third (and concluding), memoir on certain infinite products, Prof. L. J. Rogers; on the kinematics of non-Euclidean space, Prof. W. Burnside, F.R.S.

Royal Microscopical Society, October 17.—The Rev. Edmund Carr in the chair.—Dr. W. H. Dallinger, F.R.S., described a new model microscope which had been made by Messrs. Watson.—Messrs. Ross exhibited examples of their "Eclipse" microscopes.—Mr. R. T. Lewis exhibited some parasites which had been found upon a penguin from Isipingo, Durban.—Dr. H. Stolterfoth's paper on the genus *Corethron* was read by Prof. Jeffrey Bell.—Mr. E. B. Green read a paper on some parasitic growths on the root-hairs of plants. Mr. A. W. Bennett made some remarks on Mr. Green's paper.—Prof. Bell called attention to the loss the Society had suffered by the death of Dr. G. E. Blenkins, a former secretary.—Mr. F. Chapman gave a *résumé* of part of his paper on the Foraminifera of the Gault of Folkestone. The chairman and Prof. Bell made a few remarks on Mr. Chapman's contribution.—Owing to the absence of the author, Mr. Nelson's paper, on the measuring of the refractive indices of various media, was deferred to the next meeting on November 21.

CAMBRIDGE.

Philosophical Society, October 29.—Prof. T. McKenny Hughes, President, in the chair.—The officers for the ensuing session were elected as follows:—President: Prof. J. J. Thomson. Vice-Presidents: Prof. Sir G. G. Stokes, Prof. Hughes, Mr. F. Darwin. Treasurer: Mr. Glazebrook. Secretaries: Mr. Larmor, Mr. Newall, Mr. Bateson. New Members of Council: Dr. Glaisher, Prof. Ewing, Mr. F. H. Neville, Mr. E. H. Griffiths, Mr. W. B. Hardy, Mr. H. F. Baker. The retiring President, Prof. Hughes, before vacating the chair, addressed the Society. The President elect, Prof. Thomson, on taking the chair, referred to the loss sustained by science in the death of Prof. von Helmholtz.—Note on geometrical mechanics, by Prof. Sir Robert S. Ball.—On a model of the twenty-seven lines on a cubic surface, by Mr. W. H. Blythe. Mr. Blythe exhibited a model of the twenty-seven straight lines on a cubic surface, together with the drawings from which it was constructed. He stated that the 135 points of intersection of these lines can, in a special case, be determined by a simple geometrical construction without reference to any equation. Seven points taken at random on the edges of a tetrahedron are sufficient to give values to all necessary constants, and these points acting as pointers by pairs, fix the position of eleven other points; these eighteen points being used to determine others, and so on. This method is also applicable to the general case, but determines fifteen lines only; when however the sixteenth line or one point on it is fixed by a process of adjustment the remaining points can be found in the same way.—Exhibition of some photographs showing the marks made by stars on photographic plates exposed near the focus of a visual telescope, by Mr. H. F. Newall.

PARIS.

Academy of Sciences,, November 12.—M. Lœwy in the chair.—The President announced the death of M. Duchartre, and an account of this botanist's life and works was delivered by M. Bornet.—On the transit of Mercury, by M. J. Janssen. Owing to unfavourable weather, only a part of the transit was observed at Paris.—Researches on the condensation of electrolytic gases by porous bodies, particularly by metals of the platinum group; applications to the gas battery; electric accumulators under pressure, by MM. L. Cailletet and E. Collardeau. Platinum and palladium in the spongy condition, and ruthenium, iridium, and gold in the finely divided state form poles which condense electrolytic gases, and hence produce a gas battery, on subsequent connection of the poles, capable of giving up the stored energy during a short time. The storage capacity may be vastly increased by subjecting the poles to great pressure during charging. With spongy platinum and iridium a storage capacity may be attained greater than the practical capacity of lead accumulators per unit weight. Silver, tin, nickel, cobalt, and carbon do not form accumulators under these conditions with capacity increasing with the pressure.—New details concerning the Nymphæinæ of the Lower Cretaceous system, by M. G. de Saporta.—A study of the causes of saline digestion, by M. A. Dastre. Saline digestion is not due to the action of soluble ferments, and is not caused by microbes.—On the disappearance of the southern polar spot of Mars, by M. G. Bigourdan.—The transit of Mercury, by M. E. L. Trouvelot. (See our Astronomical Column.)—On an error detected in the "theory of numbers" of Legendre, by M. Dujardin.—On the representation of left-handed algebraical curves and on a formula by Halphen, by M. Léon Autonne.—On an empirical formula, by M. Pervouchine, by M. Ernest Cesàro.—Direct experimental determination of the specific heat of saturated vapour and of the heat of internal vaporisation, by M. E. Mathias. The general method given permits, by means of a double series of calorimetric experiments with an apparatus charged once for all, of the complete resolution of the problem of the calorimetric study of a substance, and shows that the specific heat of saturated vapour is susceptible of direct experimental determination.—Determination of the molecular weight of liquids, by M. Ph. A. Guye. The author gives methods of determining molecular weights of substances from a knowledge of their critical coefficients and molecular refractions and from their critical coefficients only. The relationships for a number of hydrocarbons are given, and the deduction is drawn that these hydrocarbons have the same molecular weights in the gaseous state, in the critical state, and in the liquid state.—On active amylacetic acid and some of its derivatives, by Mdlle. Ida Welt. The rotatory powers of a number of these derivatives are given. Methyl amylacetate has a rotatory power $[\alpha]_D = + 6{\cdot}71$; for the corresponding ethyl salt $[\alpha]_D = + 6{\cdot}66$. The products of asymmetry calculated for the same compounds bear the ratio 375:

343.—On the campholenes and on the constitution of camphor, by M. A. Béhal.—Researches on the oxidation of alcohols by Fehling's solution, by M. Fernand Gaud. Methyl, ethyl, and propyl alcohols yield the corresponding aldehydes and salts of the corresponding acids when the alcohol is in excess; when the reagent is in excess and the heating is prolonged at a higher temperature, salts of the corresponding acids are obtained, but no aldehyde.—Biological observations made on *Schistocerca peregrina*, Olivier, during the invasions of 1891, 1892, and 1893 in Algeria, by M. J Künckel d'Herculais.—On the swarming of Termites, by M. J. Pérez.—On the assimilation of nitrates by plants, by M. Demoussy.

BERLIN.

Physical Society, October 19.—Prof. du Bois Reymond, President, in the chair.—The President referred to the loss the Society had sustained by the death of von Helmholtz.—Prof. Boernstein demonstrated an experiment of Messrs. Elster and Geitel on the influence of polarisation on the outflow of negative electricity which may be brought about by light. The most suitable metals for the experiment are sodium or potassium or their alloys. A liquid alloy of potassium was charged with negative electricity so that the leaves of an electroscope connected with it were widely divergent. As soon as the rays of an incandescent lamp were allowed to fall on the surface of the alloy, the room being previously darkened, the leaves of the electroscope approached each other as due to an outflow of electricity. When the light was polarised by a Nicol prism it now led to a discharge only when the plane of its vibrations coincided with that of its incidence; in the plane at right-angles to the above the action of the light was reduced to a minimum.—Prof. Koenig recounted the results of his researches on the significance of visual purple. (Previously communicated to the Physiological Society on July 20. See NATURE, No. 1298, p. 492.) A discussion followed, in which the President, Prof. von Bezold, Prof. Neesen, and Dr. Rubens took part. The last-named supported Prof. Koenig's view that the fovea centralis is colour-blind for blue, by pointing out that fine blue lines in the spectrum cannot be seen by absolutely direct vision, but only by indirect vision.

Physiological Society, October 26.—Prof. du Bois Reymond, President, in the chair.—The President dwelt on the recent deaths of their honorary President, von Helmholtz, and Prof. Pringsheim, and drew attention to the more important botanico-physiological researches of the latter.—Dr. Bendix spoke on the influence of sterilising milk on its digestibility. If milk is sterilised by prolonged boiling or the passage of steam through it, a series of changes take place. The sugar is turned into caramel, and the sweet taste changes correspondingly, and, further, on cooling the fat tends to form lumps, and thus destroy the emulsion. Three experiments had been made on children between the ages of one and two years, each experiment consisting of two series. In the first, the children received either fresh milk, or such as had only been once boiled-up, together with some white bread; in the second, the same amounts of sterilised milk and bread. A comparison of the nitrogen and fat in the food and fæces showed that the sterilised milk was just as completely utilised as the unsterilised.—Dr. Cowles spoke on his cardiographic researches carried out on mammals. In his earlier experiments he had found the frog's heart to be the most suitable object, lying firmly as it does in a depression of the liver. Working with this, he had observed that as long as the heart is normally filled with blood the apex remains at rest on the surface of the liver during systole, whereas when deprived of blood it is raised at each systole. Among mammals he had not as yet found a heart so suitable for the experiment. In the dog, rabbit, and cat, the heart lies on the lung-tissue, is hence easily pushed to one side, and is thus readily displaced by any levers or other apparatus brought to bear upon it. In monkeys, also, there is a fold of the lungs lying between the diaphragm and the heart, so that up to the present he had not been able to obtain any reliable cardiographic tracings by placing levers on the outside of the mammalian heart.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (June–July 1894) contains the following papers of scientific interest:

June 9.—O. Wallach: On the relations of the carvon-series ($C_{10}H_{14}O$) and the properties of the oximes of cyclic ketones (III.). J. Hermes: On the division of the circle into 65,537 equal parts. A. von Koenen: On the geological survey of Southern Hanover.

June 23.—P. Drude: Studies on the electric resonator.

July 7.—David Hilbert: Outlines of a theory of Galois' *Zahlkörper*. K. Schering and C. Zeissig: New photographic method of registering the time and the position of the magnets in magnetometers and galvanometers. Ludwig Aschoff: Contribution to the subject of atypical epithelial proliferation and the origin of pathological glandular growths.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Nuellenkende: Prof. H. I. Haas (Leipzig, Weber).—A Laboratory Manual of Organic Chemistry: Dr. W. R. Orndorff (Boston, Heath).—Practical Methods in Microscopy C. H. Clark (Boston, Heath).—Life at the Zoo: C. J. Cornish (Seeley).—Alembic Club Reprints, No. 9: The Elementary Nature of Chlorine: Humphry Davy (Edinburgh, W. F. Clay).—Outlines of Biology: P. C. Mitchell (Methuen).—Radiant Suns: A. Giberne (Seeley).—By Vocal Woods and Waters: E. Step (Bliss).—Rhythmic Heredity: H. C. Hiller (Williams and Norgate).—Report of the Fifth Meeting of the Australasian Association, September 1893 (Sydney).—Practical Inorganic Chemistry: E. J. Cox, 3rd edition (Rivington).—Australasia, Vol. 2: Malaysia and the Pacific Archipelagoes: Dr. F. H. H. Guillemard (Stanford).—Cloudland: Rev. W. C. Ley (Stanford).—Primer of Psychology: Prof. J T. Ladd (Longmans).—Psychology for Teachers: C. Lloyd Morgan (Arnold).

THURSDAY, NOVEMBER 29, 1894.

LOCOMOTIVE CONSTRUCTION.

The Construction of the Modern Locomotive. By George Hughes. Pp. 260. (London: E. and F. N. Spon, 1894.)

OF all the many branches of engineering, that of locomotive engineering has been generally overlooked by the writers of text-books, and until quite recently the only works on this important subject were the classical works of Z. Colburn and D. K. Clerk, "Locomotive Engineering and the Mechanism of Railways," and "Railway Machinery." These works are more than twenty years old, and do not now represent modern practice, although the rules and formulæ given are largely made use of to this day, besides which the experimental data obtained by D. K. Clerk on the old Edinburgh and Glasgow Railway, some time before the year 1855, may still be regarded as of great value.

Locomotive engineers in this country owe more to the late Mr. William Stroudley than they care to admit. To Mr. Stroudley is due the thoughtful and careful designing of every part of the locomotive, from the valve motion to the damper on the ash-pan, and, thanks to his example, locomotive design has become as near a science as it is possible to be, always bearing in mind that abstract calculations are nearly useless for this purpose. A very important point in the design of a locomotive is that of facility of repairs in the running-shed. It is possible to point to more than one type of British engine where the draughtsman appears to have had entirely his own way in the design, and consequently an ordinary repair, such as changing a spring, entails the partial stripping of the engine in order to lift it high enough to effect this; whereas it should be possible to do it with a couple of jacks, just to ease the weight off the spring, take the pins out, and then replace the spring. Another similar case may be quoted. Some heavy main line passenger tank engines have recently been constructed; and should a copper stay leak badly on the side of the fire-box, the side tanks cannot be removed to get at the leak without cutting out rivets and removing the angle-iron supporting the side platform; whereas had the draughtsman been an engineer, he would have foreseen such an emergency, and provided for it. These examples are sufficient to show that when designing an engine, the position of every pin and bolt should be carefully considered, so that their removal, if necessary, will be an easy matter in the running-shed.

The volume before us, unfortunately, does not deal with design, but treats only with the manufacture of a locomotive in the works of the Lancashire and Yorkshire Railway Company at Horwich. As these works are comparatively new, it is only fair to expect to find the practice thoroughly up to date, and as the author is an assistant in the chief mechanical engineers' department, the information given may be considered to be authentic. The title chosen for the book is a little misleading, because only one type of engine is discussed; moreover, this engine is fitted with the Joy valve gear, a type of motion certainly not generally adopted by locomotive engineers.

The work is divided into six sections, and these are again subdivided when necessary. Each section describes the actual progress of the work done in that section. Taken as a whole, this book is unique; it is the only one we know of that appeals to the locomotime engineer in the language and phraseology of the works, and without the cant usually found in text-books of to-day dealing with mechanical subjects. The book being of a thoroughly practical nature, it may be as well to follow its contents in order.

Section i. deals with the boiler, the materials used in its construction, and the methods of manufacure. Steel is the material used for the shell in most cases. The author observes that if a plate is buckled, this buckling is got out of the plate by planishing, or by a multiple roller straightening machine. The former method cannot be recommended for boiler-plates, but for tank side, cab, or splasher-plates it is the common practice. The question of locomotive boiler drilling is thoroughly well gone into, but the methods described are not those of most recent practice, which may be concisely stated to be—the edges of all plates must be machined, rivet and other holes to be bored after rolling the plates to shape, and drilling all holes out of the solid. Many complicated multiple drilling machines have been constructed to meet these requirements, but it is questionable whether such complicated tools are necessary, especially when the self-pitching attachment is used, because the holes in each seam must be set out in order to find the position of the holes for the "holding together" bolts, which are usually placed 12 to 14 inches pitch, and which are usually drilled through a template in bunches before the plates are rolled. Further on the author describes a plate-bending machine capable of rolling a plate to the very edge. As such a machine is certainly very badly wanted it may be here questioned whether the one described is really capable of doing this. The old method of setting the last 4 or 5 inches with a "former" has long been condemned, but with vertical rolls the ends of the plates may be rolled to the true radius by means of a curved packing piece which holds the plate up to the movable roll, resting against the smaller live rolls behind.

We are told that the inside and outside butt strips are sheared to size, and not machined on edge; unless they are afterwards annealed, this practice cannot be commended. One cannot help being astonished at the free use of cast-steel in the boilers. This is very much up to date; but what gain there can be in using a cast-steel tee-bar in place of a rolled one for the longitudinal and sling stay attachments, cannot be seen. The crown of the fire-box is stayed with cast-steel girder-stays or roof-bars, and ferrules are used to preserve the proper distances. Surely these ferrules might be replaced by bosses cast on the stay-bar, into which the bolts would be screwed, thus strengthening the bar, and being less complicated. The foundation rings are also of cast-steel; these castings evidently require much setting and "paening." Surely they are machined inside and out, as required by good practice?

The paragraphs dealing with flanging plates and the tools used, leave nothing to be desired; they are concise and to the point. Reasons might have been given for the adoption of the "Webb" fire-hole; it seems to entail very severe treatment of the plates for no obvious purpose. There are many ways of placing the copper stays in position, and the author evidently cuts off the ends after screwing them home. Here he is behind the times: "modern practice" requires them to be cut to length in the lathe, afterwards being screwed home by a sort of stud-driver. This does away with any chance of injuring the threads by cutting them in position by eccentric portable shears, or the more barbaric hammer and chisel.

The quadruple tapping machine (illustrated) no doubt does its work very well, but it must be moved from boiler to boiler, and this entails much labour and loss of time; a far simpler tool is generally used, namely, a light radial jib carrying a movable carriage, over which the ropes run to the tool-holders, all the compensating gear being on the wall. Taken as a whole, Section i. is extremely well written, and covers a large field of detail; it concludes with the testing of the completed boiler. The hydraulic test of 200 pounds per square inch is much below the usual test-pressure in water, viz. one and a half times the working pressure, for new boilers.

Section ii., occupying eighty-seven pages, is divided into three parts. The first part deals with the iron foundry, the second on the use of steel castings, and the third describes the brass foundry. It is evident, after careful perusual, that much attention has been given to this particular branch of the works, especially the careful manner in which the mixings of the different metals is carried out, and the valuable illustrative tests showing the necessity for annealing steel castings. As an example of foundry practice, we find a full description of the moulding of a pair of twin cylinders, probably the most difficult and important piece of work occurring in a railway foundry; a few other examples are also given. In part two of this section the author wisely suggests that engineers should formulate a standard specification for the grade of material for steel castings for locomotive work, and recognise a standard size for both tensile and bending test bars. With this we cordially agree; specified tests vary far too much, and in some cases tend to make the specifying engineer a laughing-stock for contractors.

Section iii., dealing with forgings, is divided into two parts. The manufacture of tyres, axles, coupling rods, and smaller details, is well described, the usual tests being given. The method of work is illustrative of modern practice, particularly the stamping of detail work under the drop hammer. Engine tyres for India usually are required to have a minimum tenacity of from 42 to 44 tons, and with a sectional area of test piece of ½ square inch. The extension, measured over a length of 3 inches, must not be less than 20 per cent. The second part of this section deals with the manufacture of springs, among other things. Page 164 illustrates the means taken to weld a lever on to a shaft; figures C and F may make a "job," but it is preferable to fit the lever end half through the shaft before welding—that is, for a brake or a reversing shaft; for a damper shaft, a dab weld may be good enough.

In Section iv. we find a description of general copper-smith's work; and in passing we may observe that the hemispherical tops for steam dome casings are in some works made from mild steel plates in dies under the hydraulic press, as well as the upper parts of safety-valve casings and corner mouldings for fire-boxes. This reduces the cost of these items considerably.

The machine department of a locomotive works is always interesting. The machinery is in many cases of a special nature; and in railway works, where duplication is said to exist, the machines may be still more of a special type, because only one class of locomotive is made. The Horwich Works appear to be largely fitted with milling machinery, to judge by the amount of care the author takes in his descriptions. Whether milling in its competition with planing, slotting and shaping machines, will ultimately prove the cheaper process, remains to be seen. On page 204 we find the statement that all frame-plates are put on the levelling table and straightened (levelled ?) by the aid of two hydraulic jacks; further on we read that the frame template has been given up, owing to its liability to become distorted, and that a man can draw in a frame in two hours: again, it is stated that a batch of eight frames is slotted, firstly by roughing out, and secondly by a finishing cut. Surely this cannot be called modern practice? To thoroughly and truly level a frame-plate it is necessary to heat it to a cherry-red heat, and level it on a plain surface; for this reason it is usual to punch the frame-plate roughly to shape before being levelled. This punching to shape allows the frame-slotting machine to commence at once roughing out the bunch of plates. Moreover, the plate is more or less annealed by the furnacing.

The frame template generally used is made in three pieces dovetailed together, and the angle-iron bracing is conspicuous by its absence: very little trouble is caused by such a template. Surely the author has made some mistake in stating that a man can "mark out one frame, which is a two hours' job." To mark out a frame from a drawing, without a template for slotting and drilling, will take one man two days or more. Moreover, the frame-plates are not said to be planed on one side. If this is the case, much time is lost in erection and fitting the horn-blocks, assuming of course this fitting is properly done. Such a frame-plate can be planed in from three to four hours.

Case-hardened wrought-iron axle-boxes are said to be things of the past! The Midland Railway Company use nothing else, and many new engines for other railways are being fitted with them; in fact, such boxes working in chilled cast-iron or cast-steel guides are hard to beat.

The last section of this interesting book deals with the final erection of the engine, and we are glad to see that Horwich does not go in for throwing an engine together in ten hours or more, to be afterwards re-erected when the "wonder" has ceased to be talked about.

It appears that the practice of fitting the horn-blocks to the frames when in a vertical position is followed. This cannot be commended; it is far easier for the men to do it before they reach the erecting-shop, when laying on trestles; the holes can then be opened out, and the bolts or cold rivets driven in comfortably. Pianoforte wire has long been abandoned for squaring over cylinder centre-lines by contractors, for the reason that it can be bent between the fingers, and thrown one way or another by the men. The three-inch tube for setting the slide-bars cannot be trusted for accurate work, owing mainly to the end drooping by its own weight, and slackness in the glands and temporary front cylinder cover. Squaring over the frames is now done by a long square, one arm being placed through the driving horns, and held against them. The distance is then measured from the leading and trailing horns to the other arm of the square when held in the four positions. If the frames are square, these measurements should agree, if the horns are similar throughout. A woven silk cord is best for lining up the frames and cylinders.

The volume concludes with a lengthy description of the Joy valve gear, a gear not generally used in locomotive work. It is a pity the author does not treat the so-called Stephenson link motion in a similar exhaustive manner. In conclusion, we must congratulate the author on having written the first readable and accurate book on the construction of the locomotive engine. He has treated his subject in a masterly way; he describes, as a rule, the most recent practice in a thoroughly professional manner. The work is well and copiously illustrated, and will be of great use to those who take an interest, either professionally or in an amateur way, in the construction of the locomotive. N. J. LOCKYER.

INDO-MALAYAN SPIDERS.

Malaysian Spiders. By Thos. and M. E. Workman. Parts 1, 2, and 3. (Belfast: Published by the Authors, 1894.)

THE material upon which this work is based was obtained by the authors during a recent visit to the East Indies; and since the entire collection has been submitted for examination and description to Dr. Thorell, who has made a special study of the Arachnida of this quarter of the globe, it may be taken for granted that the species have been as satisfactorily identified as is possible. Most of them, whether old or new, have been already described in detail by this specialist. But his systematic zoological work, although in its way of unrivalled excellence, is open to two objections. We have, in fact, heard it alleged, firstly, that the span of human life is too short, and the number of existing spiders too great, to admit of deserving attention being paid to his exhaustive descriptions; and, secondly, that a deal of vexatious trouble and valuable time might be saved by the addition of a few figures to the overwhelming amount of text. It is evident that Mr. and Mrs. Workman have realised the full force of these two objections; for this book of theirs may be briefly described as a supplement designed to make good the defects in Dr. Thorell's report upon their collection.

The work is being issued at intervals in shilling parts, of which three, comprising in all twenty-nine plates, have up to the present time appeared. Every species is illustrated by a hand-coloured figure, together with outline sketches of structural details; and accompanying each set of figures is an explanatory page of text, giving the name and synonymy, the affinities and distribution of the species, and some measurements of the type-specimen. Moreover, in some instances interesting items of news respecting habits, &c., are added; and in the case of the orb-weavers, a figure of the web characteristic of the species is engraved on a separate plate. It is this part of the work, we feel sure, that will prove of the greatest interest to the student of spider-life. Even the pure systematist may learn from it valuable facts bearing upon his aspect of the subject. For the figures and descriptions of the webs afford indisputable evidence that remotely allied genera may construct snares of substantially the same kind, as may be seen by a comparison of the nests of *Callinethis*, *Gea*, *Argyroëpeira*, *Epeira*, and *Gastracantha*, represented in parts 1 and 3; and that within the limits of the same genus, species may be found that spin webs differing widely in important points of structure, as a glance at the figures of the webs of *Epeira calyptrata*, *unicolor*, and *beccarii*, in parts 1 and 3, will show. Clearly the importance of these facts must be steadily kept in view by those who base their classification of spiders on the structure of the webs.

The discovery of the snare of *Uloborus quadri-tuberculatus* has given rise to a curious problem. This web is always spun on the pine-apple, and is of a peculiar basket-shape, the peculiarity consisting in the remarkable adjustment that is exhibited between the structure of the web and that of the plant. But the pine-apple is a native of South America, and has only of late years been introduced into Singapore; so that if the spider is truly a native of the latter place, it has evidently rapidly modified its spinning instincts in response to the slight change in its environment brought about by the introduction of the pine-apple. Before such a conclusion, however, can be looked upon as an established fact, evidence must be produced that the spider and the plant were not concomitantly brought from the Neotropical to the Oriental region.

Another very interesting fact is noticed in connection with *Argyroëpeira striata*. We are told that this spider, which is normally of a bright golden tint, "has the power of darkening down its brilliant colouring when frightened." (part 3, p. 19.) The importance of this observation is greatly enhanced by the independent discovery made by Mr. H. H. J. Bell, and published in NATURE (vol. xlvii. p. 558), to the effect that a West African species of *Argiope* possesses the same faculty of rapidly varying its colour under the stimulus of changing surroundings.

From what has now been said, it may be judged that the value of this book, as an addition to the literature of spiders, is both great and unquestionable. But it is impossible to shut one's eyes to the fact that its general excellence is slightly marred by a few blemishes, which, at the risk of appearing ungrateful, we think it our duty to point out; not, be it understood, with the object of fault-finding, but in the hope that none of them may be copied by other authors, and that some, at least, may not reappear in succeeding parts of the work.

In the first place, respecting the method of publication, it is a pity that both preface and introduction have been altogether omitted, and that species belonging to such widely different families as *Oxyopidæ*, *Attidæ*, *Thomisidæ*, and *Epeiridæ*, should be indiscriminately mixed, as they have been in part 1. With regard to the preface, we hope that the authors will see the application of the maxim, "Better late than never"; and although the adage, "What is done cannot be undone," holds good in the case of the parts already issued, we should like, nevertheless, to see a little more method displayed in the grouping of the species contained in the forthcoming parts.

In the second place, since more than one species is now for the first time made public property, it may prove as serious an oversight as it is an irreparable one, that the exact date of the issue of the several parts has not been permanently recorded on the title-pages. Moreover, these new species, instead of being rendered conspicuous as such by the familiar symbol *n. sp.*, are ascribed to Dr. Thorell, with the simple addition of the words "Thorell MS." No doubt the considerations of courtesy expressed by this ascription are worthy of all praise; but it will be as well to bear in mind that the species are for the first time described and figured in a work, not by Dr. Thorell, but by Mr. and Mrs. Workman. It is, consequently, within the bounds of probability that some of us may feel inclined to question the right of the latter two authors thus to constitute the former the founder of these species; seeing that his sole claim to the title rests upon an unpublished suggestion respecting their names, coupled with a privately expressed opinion that they were new forms.

We should also like to suggest that a little more precision in the printing of the figures would greatly add to the value of the plates, without much increasing the cost of their publication. If this and the other alterations we have ventured to propose are adopted for the remaining parts, it is certain that the work, when complete, will rank as one of the most important contributions to the natural history of spiders that has appeared in the last quarter of this century. R. I. Pocock.

THE PLATEAU REGION OF SOUTHERN FRANCE.

The Deserts of Southern France; an Introduction to the Limestone and Chalk Plateaux of Ancient Aquitaine. By S. Baring-Gould, M.A. With illustrations. In two volumes. (London: Methuen and Co., 1894.)

The region described by Mr. Baring-Gould, lies, roughly speaking, to the south and south-west of Auvergne, forming a kind of border-land to that country and the Cevennes. Most of it goes by the name of Les Causses. This is a limestone region, furrowed deep by gorges, and pierced by caves. On the eastern side it rises, in three steps, from the neighbourhood of the Gulf of Lyons to the central *massif* of ancient granite and schists and of comparatively modern volcanic-rock; on the western side it falls, in like manner, to the sandy lowlands on either bank of the Garonne.

The scenery of these gorges is always striking and often grand; the finest cañons being those traversed by the Lot and the Tarn. Mr. Baring-Gould's first mention of the former river may serve as an example of the characteristic scenery.

"Near its cradle it passes under the frowning Causses of Sauveterre, then it cleaves the limestone of the Rouergne, and afterwards winds and writhes like a serpent through the Causses of Quercy. Everywhere, at every stage, it affords surprises; the scenery is sublime and quaint. On both sides the cliffs are encrusted with castles and domestic habitations, built half into the crags. Churches and towns stand on the tops of the cliffs, and look down on the boats that glance by. In its sinuosities it washes overhanging scars, without leaving soil at their feet on which to plant a foot, whereas an alluvial meadow, rich and rank, is on the farther bank; then, suddenly, the capricious river turns to the opposite side and treats it as the first. Consequently a road was only to be carried up the Lot valley by means of tunnels and bridges."

Among the natural wonders of this region, its caves and swallow-holes are not the least. These Mr. Baring-Gould seldom ventured to examine in person, but he quotes extensively from M. E. A. Martel, one of their most adventurous explorers, and gives some excellent illustrations. The latter remind us of similar features in the Carinthian Alps to the north of Trieste, and in the Carboniferous Limestone districts of our own country, with which Prof. Boyd Dawkins has made us familiar in his book on "Cave Hunting." In exploring these underground regions a human interest is not always wanting; for the investigator may come across the skeleton of a suicide or the remains of prehistoric man, while the stalactites are sometimes remarkably fine.

It is unfortunate that Mr. Baring-Gould did not get some friend, more expert in geology, to look over the proofs of his book. His references to that subject are often wanting in clearness and precision, and thus are sometimes rather perplexing. This is perceptible even on the title-page, where he speaks of the "limestone and chalk plateaux." But "chalk" *is* a "limestone," so we conclude that the author uses the term in a limited sense, whether it be the descriptive or the geological. But if the former, then, so far as we are aware, the soft white limestone which we call chalk does not occur in the Cretaceous system of Southern France; and if the latter, some distinctive epithet, such as "Jurassic," should have been inserted before "limestone." Such a statement as this also is puzzling: "The lowest stage (of the Causses) . . . is of chalk with a layer of lias above it in places." This is incomprehensible, unless Mr. Baring-Gould uses chalk merely as a synonym for light-coloured limestone (which he often does, unless we misunderstand him), or some strange faulting has occurred (which seems highly improbable). The following passage, also, will hardly satisfy either a zoologist or a geologist:

"The Dolomitic limestone is held to be coral rock built up under water by the industrious insect that is at present forming reefs and islands in the Pacific. At the time when these tremendous masses were composed, the lias lay at the bottom of a warm shallow sea, and on its banks the coral worm worked. Gradually the bottom of the sea sank, and as it sank, so did the insects build upwards towards the light and warmth. After a lapse of ages the whole was upheaved. . . . As the construction is vertical, the structure is vertical, and as the coral insects twisted and turned about sponges, masses of seaweed, and avoided cold currents, the whole mass of rock abounds in hollows in which water accumulates, and in passages through which rivers run."

These, however, are trifling blemishes, which can be readily put right in a second edition. The book is delightful reading, and is full of interesting information, at which we have only time to glance. Mr. Baring-Gould, among other things, gives a good account of the curious fire-hills of Cransac, produced by spontaneous combustion, in the coal basin of Decazeville and Aubin. His description also of the irreparable mischief wrought by the reckless destruction of forests, is well worth reading, for it must be remembered that the weird desolation of the limestone plateaux is a thing of comparatively recent date, and an indirect consequence of the French Revolution. Of the rock shelters of the "reindeer age" in the valley of the Dordogne and of other rivers, he has much to say, and of the dwellers in "holes of the rock" down to the present day; for these caves have been enlarged, or faced with masonry, or actually excavated, at various dates, and in some cases are still inhabited. Of the dolmens and other megalithic remains which are common on the plateaux region, Mr. Baring-Gould writes as one who has made a study of the subject. Perhaps some of his ethnological speculations may not meet with universal acceptance, but they are, at any rate, worth considering. The book contains many curious bits of folk-lore, as we might expect, and narrates sundry remarkable historical episodes in the mediæval struggle between France and England, and in the sanguinary conflicts of Huguenots and Romanists. A chapter is also devoted to the romantic, though often discreditable, story of Joachim Murat, who was born at a dirty little "bastide" of the same name on the Causse de Gramat, near the source of a tributary of the Lot. The book, in short, while it indicates the author's cultivated tastes and wide range of reading, directs the attention of travellers to a region of singular and varied interest, which hitherto has received but little notice even from the French themselves. It is only inadequately described in Reclus' great work, "Géographie Universelle." It has not, however, escaped the indefatigable emissaries of Baedekker, who gives, in the volume on Southern France, a succinct account of the district, evidently founded on personal knowledge. Armed with the little red book, and Mr. Baring-Gould's more bulky volumes, a rich reward undoubtedly awaits the visitor. The guide-book will direct his steps aright; Mr. Baring-Gould's pleasantly written and admirably illustrated volumes will give him abundant information about the chief points of interest, whether physical, archæological, or historical, and will be an unfailing resource during those hours of enforced leisure, which, on a journey, are apt to become tedious.

T. G. BONNEY.

OUR BOOK SHELF.

An Elementary Treatise on Theoretical Mechanics. Part I. Kinematics. Part II. Statics. By Alexander Ziwet, Assistant Professor of Mathematics in the University of Michigan. (London and New York: Macmillan and Co., 1893.)

AMERICAN mathematicians have always followed the system of the French and continental school, so that the progress of the American student in analytical development has not been arrested and stunted by the excessive reverence of the Newtonian methods prevalent in this country.

According to the continental system a student is introduced at the earliest possible stage to the Cartesian methods of geometry and to Leibnitz's extensions in the domain of the Differential and Integral Calculus; and then, even with a comparatively small equipment of analytical knowledge, hardly extending beyond an acquaintance with the notation, he is prepared to study and appreciate a work like the present; while the English student is kept back by clumsy antiquated methods, on the pretext of developing his geometrical and general reasoning powers.

This work is intended as an introduction to the science of theoretical mechanics, adapted to the particular wants of engineering students who, with the characteristic practical energy of their race and age, will not desire to be kept marking time over the rudiments.

The general treatment of the subject is elegant and complete, and valuable collections of illustrative examples are introduced at the different stages. One of these, however (ex. 6, § 276), caught the eye, as requiring amendment; as also the Fig. 29 of the catenary.

An old friend, the problem of the beam in a bowl—in other words, of a spoon in a teacup—given as ex. 20, § 151, deserves separate discussion, and a complete solution in the text.

The present opportunity is favourable for expressing to Prof. Ziwet the thanks of mathematicians in this country for his valuable Report of Prof. Klein's Lectures on Mathematics, called the "Evanston Colloquium," held before members of the Congress of Mathematics in connection with the World's Fair at Chicago, at North western University, Evanston, Ill.

G.

By Order of the Sun to Chile to see his Total Eclipse, April 16, 1893. By J. J. Aubertin. Pp. 152. (London: Kegan Paul, Trench, Trübner, and Co., 1894.)

TWO years ago Mr. J. J. Aubertin, having seen a copy of NATURE for October 13, 1892, containing a letter on the then coming solar eclipse, went home and dreamed a dream. In his vision the Sun visited him and ordered him to gird up his loins, and go to the desert of Atacama and watch the eclipse. This brief explanation is necessary in order to account for the rather clumsy title of the book before us. Mr. Aubertin, regardless of the belief that dreams should be reversed, and that he was seventy-five years of age, travelled to Chile, and, meeting Prof. Schaeberle there, became one of the eclipse party. He was, however, more an interested layman than a scientific observer, and therefore his book is of very little value to astronomers. In fact, the book is chiefly taken up with tittle-tattle of interest to very few beyond the parties concerned. A picture of the corona, as seen by the author, is very pretty, and compares favourably with the impressions recorded by observers of the phenomena before photography monopolised the field as a coronal artist. But at the present time, the results of visual observations of the corona are regarded with suspicion, and rightly, for they never afford any very definite information as to the true form and structure of the sun's surroundings. However, Mr. Aubertin faithfully records what he saw, so his observation must be accepted. The book contains Prof. Schaeberle's photograph as a frontispiece.

Reise nach Südindien. Von Emil Schmidt. Mit 39 Abbildungen im Text. (Leipzig: Wilhelm Engelmann, 1894.)

HERR SCHMIDT'S book is a plain, straightforward narrative of a tour through Southern India, in the course of which he visited Madras, Travancore, made an excursion to Cape Comorin, proceeded by Trivandrum to Cochin, and thence by Coimbatore to the Anamalay Hills, going afterwards to the Nilgiris, and finishing at Calicut. The object of the journey was mainly to study the native peoples, and numerous ethnological photographs give a certain value to the book. There is, however, nothing new in the way of an important contribution to science in the work, which is most interesting as showing the impressions produced on an intelligent and observant German by a visit to Southern India. The style is lively, but perfectly serious, and cannot fail to be of much value in Germany, where it appears few books have been published dealing with the lighter aspects of Indian life. It is pleasant to note that Herr Schmidt found the English officials and planters everywhere very hospitable and cordial, ready to assist him in his inquiries as to the people, and able to give him much valuable information on the subjects which he was studying.

By Vocal Woods and Waters. By Edward Step. Pp. 254. (London: Bliss, Sands, and Foster, 1894.)

A RESURRECTION book, made up of papers originally contributed to *Good Words*, *Leisure Hour*, *Sunday Magazine*, *Silver Link*, and other periodicals. The author is well known as a close observer of nature, and he has the amount of poetry in his composition essential in a writer on popular natural history. The book is nicely printed and illustrated.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Acquired Characters.

IN reference to the question as to how far the signification of the term "acquired characters" may usefully be extended beyond the precise limit given in Lamarck's two laws (quoted in my letter of November 15), or what phenomena may be brought into close relationship with those indicated by Lamarck, the following considerations, will, I think, be found useful.

Let us consider a relatively stable local "race" of some species of organism. The race is found to present a certain range of variation, but has an average character; and cases approximating to the average are so far more numerous than departures from it, that for our immediate purpose we may leave the aberrant individuals out of account. The average specific character is a matter which may be determined by measurement and weighing. It can be stated in numerical form as to length of such and such parts, breadth and depth of other parts, weight (*i.e.* amount) of pigment or other chemical product here or there. We know by experiment that these quantities can be altered in immature individuals *within limits* by changing the physical conditions in which the individual is placed. These physical conditions are (roughly speaking) such measurable quantities as those relating to temperature, light, mechanical strains, moisture, and varying amounts of chemical compounds or elements operating on the organism through its absorbing surfaces (respiratory organs, digestive organs, integument).

From such experiments we are led to conclude that without destroying the life of an individual many characters can be increased in quantity, but that there is a limit beyond which they cannot be so increased; and that many characters can be reduced in quantity in the same way in an individual without destroying its life, but that here also there is a limit. Hence it seems that we are justified in distinguishing the "potential" from the "actual" characters of an organism.

This *potentiality* of the individual is something inborn or congenital. On the other hand, the *actual* quantitative condition of the average characters of a naturally-occurring assemblage of individuals is necessarily to some extent the result of the operation of the measurable physical agencies which constitute the normal environment of the species or race. (The range of difference, it may here be noted, between the potential and the actual characters of a species as thus indicated, is found to differ very greatly in different species and in regard to different parts of the organism.) Thus then every individual exhibits certain quantitative characters, the amounts of which are *determined* by the operation on the individual of given and related quantities of external agencies. To a character thus quantitatively determined, some writers have extended the term "acquired character," inasmuch as it is not the congenital potential character in its purity (if such a thing were possible) which we thus contemplate, but the congenital character as moulded, increased, or restrained by surrounding conditions. But whilst I am very decidedly of opinion that a consideration of this moulding, expanding, or restraining influence of the normal environment is likely to throw important light upon the implications of Lamarck's doctrine, I agree most emphatically with Mr. Francis Galton in thinking that the use of the term "acquired characters" must be limited, as indicated by Lamarck's own statement, to characters, "which are regularly found in those individuals only which have been subjected to certain special and abnormal conditions" (to quote Mr. Galton's words). The word "acquired" was used by Lamarck, and should continue to be used as pointing to an acquisition, under *new* conditions, of *new* character or characters, distinct from the normal characters which form, as it were, the starting-point, however determined or brought into existence.

It is, however, true that the difference between the actual characters of an individual organism as compared with its potential characters—a difference the origin of which may be expressed by calling the former "responsive characters"—is of the same order whether the actual characters are determined in their amount by the normal environment of the race, or by abnormal quantitative changes of that environment.

And it seems to me, that in considering this we are led to the conclusion that the second law of Lamarck is a contradiction of the first. Normal conditions of environment have for many thousands of generations moulded the individuals of a given species of organism, and determined as each individual developed and grew "responsive" quantities in its parts (characters); yet, as Lamarck tells us, and as we know, there is in every individual born a potentiality which has *not* been extinguished. Change the normal conditions of the species in the case of a young individual taken to-day from the site where for thousands of generations its ancestors have responded in a perfectly defined way to the normal and defined conditions of environment; reduce the daily or the seasonal amount of solar radiation to which the individual is exposed; or remove the aqueous vapour from the atmosphere; or alter the chemical composition of the pabulum accessible; or force the individual to previously unaccustomed muscular effort or to new pressures and strains; and (as Lamarck bids us observe), in spite of all the long-continued response to the earlier normal specific conditions, the innate congenital potentiality shows itself. The individual under the new quantities of environing agencies, shows *new* responsive quantities in those parts of its structure concerned, new or "acquired" characters.

So far so good. What Lamarck next asks us to accept, as his "second law," seems not only to lack the support of experimental proof, but to be inconsistent with what has just preceded it. The new character, which is *ex hypothesi*, as was the old character (length, breadth, weight of a part) which it has replaced—a response to environment, a particular moulding or manipulation by incident forces of the potential congenital quality of the race—is, according to Lamarck, all of a sudden raised to extraordinary powers. The new or freshly-acquired character is declared by Lamarck and his adherents to be capable of transmission by generation; that is to say, it alters the potential character of the species. It is no longer a merely responsive or reactive character, determined quantitatively by quantitative conditions of the environment, but becomes fixed and incorporated in the potential of the race, so as to persist when other quantitative external conditions are substituted for those which originally determined it. In opposition to Lamarck, one must urge, in the first place, that this thing has never been shown experimentally to occur; and in the second place, there is no ground for holding its occurrence to be probable, but, on the contrary, strong reason for holding it to be improbable. Since the old character (length, breadth, weight) had not become fixed and congenital after many thousands of successive generations of individuals had developed it in response to environment, but gave place to a new character when new conditions operated on an individual (Lamarck's first law), why should we suppose that the new character is likely to become fixed after a much shorter time of responsive existence, or to escape the operation of the first law? Clearly there is no reason (so far as Lamarck's statement goes) for any such supposition, and the two so-called laws of Lamarck are at variance with one another. To push the matter further—in those cases in which experiment has been made, it has been found that a character acquired by an individual removed from the operation of a related condition normal to the race of which that individual is an example, is replaced by the old character when the old condition is restored in the environment of the offspring of that individual. No doubt I shall be challenged to produce evidence confirming this last statement. I admit that carefully studied and conclusive instances are not very numerous, but I refer to such cases as the non-transmission (*a*) of plus or minus variation in pigment produced in individuals by greater or less exposure to sun-light; (*b*) the effects of dry or moist climate on individual plants; (*c*) the effects of change of diet on individual animals; (*d*) the effects of increased use of muscles in men and animals.

It seems that we are driven to the conclusion that the causes which have been active in producing changes the accumulation of which amounts to specific, generic and larger differences, must be causes which are able to act upon the potential congenital quality of the individual, and that there is no reason for associating the somewhat superficial and late responses or reactions of the parts of a growing individual to normal or abnormal forces of its environment with that more subtle and profound disturbance, which is permanent and affects the potential character of the germ, and more or less of all the germs derived from it.

At any rate this is the absolutely unanimous testimony of all those observers, in all countries and in all ages, who have been practically concerned (often with vast pecuniary interests at stake) in the production of relatively permanent new races of animals and plants. Breeders of horses, cattle, sheep and dogs, pigeon and poultry-fanciers, crop-growers, nurserymen, tulipomaniacs, and the like, have never in any single instance put the Lamarckian principle into practice. On the contrary, they laugh it to scorn. Not one of them ever produced a new race by moulding the parents. But, on the other hand, they *do* subject the selected parents to novel and disturbing conditions, to which the changed characters of the *offspring* (not of the parents) have no "responsive" relation; they cross-breed here and cross-breed there, until the "specific potential" is broken-down, and strange unlooked for varieties are born and grow up irrespective of normal or abnormal environment. From these congenital variations they select desired forms, and perpetuate them with perfect assurance and security.

For the present I see no evidence of a production of new races on the face of the earth, excepting by the method adopted by these men, viz. by the selection of congenital variations; such congenital variations being produced as the result of (but without any direct adaptational relation to) a disturbance of the material of the reproductive particles of both sexes; that disturbance being increased, if not determined, by changed environment of the parental organisms or the coupling of remote strains.

E. RAY LANKESTER.

Oxford, November 17.

The Present State of Physiological Research.

THE extracts given in NATURE of November 15, from an article by Prof. Max Verworn, of Jena, on "Modern Physiology," will serve to draw the attention of biologists to the reawakening of interest which is now evinced by many physiologists in regard to the fundamental phenomena exhibited by living things. As the opinion of physiologists is expressly invited in reference to the questions raised in this article, I venture to express my own as being in the main the same as that of Prof. Verworn.

It seems to me an obvious truism to say that the methods which can ensure a real advance in general biological knowledge must be those in which comparative physiology takes the lead. In my recent presidental address to the Liverpool Biological Society I urged the establishment of laboratories for the systematic study of the comparative physiology of the simpler organisms, the end in view not being the elucidation of the functions of organs with an *arrière pensée* as to their relation to man, but the examination of the activities for their own sake, since this inquiry forms the only means of approaching the mystery which enshrouds the essence of living existence.

The determination of the reactions of simple organisms to physical changes (stimuli), and the grouping of such resultant effects carried out systematically, form a line of physiological inquiry of transcendent importance, both because of its large scope and fundamental character, and because it opens the way towards the partial elucidation of the physiologist's real problem. This problem is the one involved in the question, to what extent all living phenomena are to be regarded as reaction phenomena? Are we, on the other hand, compelled to postulate the existence in every living thing of a *deus ex machina* which can, if it will, act independently of every physical stimulus, a so-called "vital force"?

Prof. Verworn is right in forcing upon the attention of physiologists the paramount necessity for work of this kind. I venture, however, to point out that he has not done justice to the judgment of his contemporary physiologists if, as I imagine, he has been led to infer from the character of the mass of current physiological work, that they do not realise the importance of such comparative physiology. But to realise the importance of an inquiry and to be able to carry that inquiry into effect, are unfortunately by no means identical positions.

There are undoubted obstacles to the latter, however ardently we may desire its fulfilment.

In the first place physiology is, in this country, more or less shackled by its position. It owes everything to medicine. Its laboratories are adjuncts to medical schools, its professors must take their share in the teaching in such schools, and this teaching is essentially connected with human physiology.

The debt, which as physiologists we owe to medicine, is one which we gratefully acknowledge, but even with the thanks on our lips we may be supremely conscious of the chains which still hang on and impede the debtor. It is this close relationship which, in my opinion, has served to accentuate the separation between physiology and the science of which it properly forms part, biology; a separation which is now almost a judicial one, and if unchecked may become an actual divorce. It is rare to fine a physiologist who has been highly trained in zoological investigation, and rarer still to find a zoologist who has attempted to perfect himself in the methods used in physiological laboratories. Yet the appropriate blend is essential for the advent of those comparative physiologists who alone can do full justice to the systematic inquiry now advocated.

Another difficulty in this country is undoubtedly due to the scanty pecuniary help afforded to scientific work which is neither technical nor directly concerned with what is regarded as the public good. Physiology, to-day, is maintained in Great Britain solely because it forms an essential part of a specialised technical education, that of the medical student; it is not maintained in order to inquire into the mystery of living things as such.

In order to adequately develop such an inquiry as this, it would be necessary to have a new department furnished with the equipment of both a zoological and a physiological laboratory, and with skilled workers who have leisure to prosecute their investigations. Since this means money, its full establishment may have to be postponed until that pious benefactor appears whose dawn even a Bodleian librarian has now anxiously to await.

Finally, I do not think the outlook is so discouraging as Prof. Verworn seems to believe, nor that "we are making no progress in physiology."

He admits that during the last twenty years we have attained to a precision in our experimental methods such as excites the astonishment of the uninitiated; and surely the mastery of method is the first step, and that an invaluable one, towards its future more fruitful employment. I do not imagine that even the systematic physiological investigation which he advocates, will involve the employment of new methods to the exclusion of old ones; it is the material which will be novel, not the entire experimental technique. Isolated instances of the application to simple excitable organisms, of such physiological methods as have been employed in elaborate detail for the investigation of muscle, nerve, &c., are well known to us all, and to no one better than Prof. Verworn; the real desideratum is surely that the instances should be no longer isolated, but form part of a broad systematic inquiry.

FRANCIS GOTCH.

University College, Liverpool,

Wilde's Theory of the Secular Variation of Terrestrial Magnetism.

MR. WILDE's reply in NATURE of October 11 to my letter of criticism in the same of August 9, with respect to his communication to the Royal Society, contained in the *Proceedings* for March 1894, has just come to my attention.

As the letter consists entirely in an attempt to show the inaccuracy and unreliability of my statements with respect to the inclination-observations made at St. Helena, behoves me to confine my own remarks to this matter. In order that my explanations may be understood, the table previously given is here reproduced.

No.	Date.	Observer.	Observed inclination.	Wilde's inclination.	Observation – Theory.
1	1700	Hansteen Chart	2° S.	3°·9 N.	–5°·9
2	1754·3	La Caille	9·00	0·5 S.	–8·5
3	1771·4	Ekeberg	13·00	3·5	–9·5
4	1775·4	Cook	11·42	4·0	–7·4
5	1780	Hansteen Chart	10·5	5·1	–5·4
6	1825·0	Duperrey	14·93	14·7	–0·2
7	1840·1	Ross	18·27	18·5	+0·2
8	1842·3	Belcher	17·00	19·0	+2·0
9	1846·8	Smyth	19·39	20·5	+1·1
10	1890·1	U.S.C. & G.S	29·65	33·8	+4·1
11	1890·1	,,	31·18 S.	33·8	+2·6

This table is in every respect the same as originally given with the exception of the value for 1700, the erroneous value of 11°·5 S. having been given instead of 2° S. Owing to my sojourn in Europe being but a temporary one, I have not with me all my data, and so cannot ascertain definitely how this error crept into my table. My original scaling was probably 1·5 S., which by a copying blunder may have been converted into 11·5. This, however, I cannot control now. It would have been a most natural inference on Mr. Wilde's part if he had ascribed this to the "printer's devil," all the more so as no use whatever was made in the text of my communication with this value. On account of so apparent an error he casts a slur upon my trustworthiness in general in regard to terrestrial magnetic matters. Such a poor method of argument reveals the weakness of his position.

Furthermore, with reference to this table, Mr. Wilde says: "I regret to observe that L. A. Bauer, in his intolerance of the magnetarium results, has inserted in his table guesses of his own for observations, which are very wide of the truth." I can find no excuse whatever for this statement. Mr. Wilde has acknowledged that he possesses a copy of Hansteen's "Magnetisms der Erde." Let him turn to Tafel II.: "Neigung der Magnetnadel," p. 36, and he will find the following observations given for St. Helena:—

Observer.	Date.	Inclination.
De la Caille . .	April 10, 1754	9° 0′ S.
Ekeberg. . . .	May 19, 1771	13 0 S.
Cook	May 17, 1775	11 25 S.

Position assigned by Hansteen: latitude 15° 55′ S., longitude 11° 52′ E. of Ferro, or 354° 12′ E. of Greenwich. By inspecting the table given above it will be seen that these form Observations Nos. 2, 3, and 4. No. 5, as stated, is taken from Hansteen's Chart for 1780. Mr. Wilde does not appear to question this value, nor the remaining ones, which can be easily found in Sabine's "Contributions to Terrestrial Magnetism." He will, furthermore, find that Hansteen had so much faith in the early observations, which Mr. Wilde insinuates are untrustworthy, that in 1857 he made use of all the observations known up to that time, viz. Nos. 2, 3, 4, 6, 7, 8, and 9, for the establishment of a periodic formula representing the secular variation of the inclination during this epoch. These investigations of Hansteen's can be found in "Den magnetiske Inclinations Forandringer i den nordlige og sydlige Halvkugle af Christopher Hansteen," Copenhagen, 1857, –4°. Hansteen, by a least square adjustment of the observations named, derived the following interpolation formula:—

$$i = -13°58'·455 - 5'·44405\,(t - 1800) - 0'·001013\,(t - 1800)^2.$$

i denotes the inclination at the time t, south inclination being reckoned as minus. This formula at the utmost should not be used more than ten years prior to 1754, nor ten years later than 1846. The following table shows how the values computed with this formula agree with observation.

Date.	Observed inclination.	Computed inclination.	O. – C.
1754·28	– 9°·00	– 9°·85	+0°·85
1771·38	–13·00	–11·38	–1·62
1775·38	–11·42	–11·77	+0·35
1824·96	–14·93	–16·26	+1·33
1840·10	–18·27	–17·66	–0·61
1842·35	–17·00	–17·87	+0·87
1846·79	–19·39	–18·28	–1·11

From this comparison it will be seen that the formula represents the observations fairly well. Let us compute then with it what the inclination would be in 1747. We obtain –9°·2. Now Mr. Wilde's magnetarium has given us for this date the value 0°·0. Hence there is an outstanding difference of about 9°, which he has made no attempt to explain otherwise than by insinuating that I have put "guesses" in my table, or that the observations are untrustworthy. The burden of the proof that the observations are not trustworthy, rests with Mr. Wilde. Anyone, who has made any endeavour to familiarise himself with the literature of the subject of terrestrial magnetism, will know that it is an old story for theorists to characterise observations as doubtful if they do not happen to agree with their theory. I am willing to admit that the early inclinations in such a locally disturbed region as St. Helena, perhaps, cannot be depended upon nearer than to 2° or 3°; but, if Mr. Wilde will pardon my scepticism, I do not believe that it is possible for him to reproduce any inclination with his magnetarium that can be relied upon even to this extent. Hence, it is fair for me to compare the magnetarium results with that of observations (so long as the latter have not been overthrown) without consideration of the probable error of either result.

Mr. Wilde appears to have thought his position proven when he found that I made an error with respect to my first value. But even with the value as given by him, the outstanding difference is 5°–6°, with which he appears perfectly satisfied. If he will permit me a probable error as large as he permits himself in the establishment of his theory with his magnetarium, I can supply him with a dozen periods that will satisfy observations as well as his magnetarium. I would like to refer him to a recent attempt by Dr. Felgentraeger, who endeavours to prove the universality of the secular period by establishing periodic formulæ upon the basis of most carefully collected material. He deduces a period of 477 years—instead of Mr. Wilde's 960—upon the basis of the declination observations made at London 1580–1882, and Paris 1541–1890.[1] Adopting this period he found that he could represent exceedingly well the observations made at London, Paris, Rome, Clausthal, Chambersburg (U.S.A.), Rio de Janeiro, Cape of Good Hope, and Cape Comorin. Here we have a more extensive comparison than Mr. Wilde has given us, and we find a better agreement with observations with a period one-half of his! In this brief communication I cannot set forth my own position with respect to the secular-variation period. I hope to present Mr. Wilde with a copy of my investigations some time in December.

With respect to my opinion of the magnetarium in particular, I may say that my criticisms made thus far have applied solely to the theory as evolved from the magnetarium results, and do not touch the magnetarium as a valuable instrument of research. Indeed, I think much good can be accomplished with it. Mr. Wilde has made a most laudable attempt to reproduce mechanically the complex phenomena of terrestrial magnetism, and if the achievements with his ingenious mechanism had not received the publicity they did, or had been properly interpreted, my criticisms would never have been made. That he has not succeeded in giving us a better representation is no fault of his, but owing to the complexity of the phenomena.

The fact that Mr. Wilde has succeeded, by an arbitrary distribution of magnetic matter in his magnetarium, in representing the *distribution* of terrestrial magnetism for the year 1880 apparently so well, is no proof of his secular-variation theory or his period, which plays no part in determining the distribution. Nor is the fact that with *his* distribution of magnetic matter he gets a good representation a proof that *that* is the actual distri-

[1] Dr. W. Felgentraeger: Die längste nachweisbare Säculare Periode der erdmagnetischen Elemente, Teil 1: Deklination. Inaug. Diss. Universität zu Göttingen, Göttingen, 1892. Buchdruckerei von Louis Hofer.

bution prevailing in the earth. It can be demonstrated as a mathematical fact that in the absence of terrestrial magnetic observations within and without the earth's surface, an infinite number of different distributions is possible that will satisfy the effects observed on the surface alone.

In conclusion, it is my duty to make one more explanation. Mr. Wilde understood from my first letter that I am still in the employ of the U.S. Coast and Geodetic Survey. In view of the fact stated by him, that he sent, at considerable trouble and expense to himself, a duplicate of his magnetarium to the "Survey," and, hence, it might appear that it was somewhat discourteous in a member of the "Survey" to thus criticise him publicly, I may say that I severed my connection with the Survey two years ago, and that my criticisms have been made without any knowledge whatsoever of what has been accomplished with it by the "Survey."

Friedenau bei Berlin, October 31. L. A. BAUER.

Boltzmann's Minimum Theorem.

MR. CULVERWELL's letter of October 25 ought to have received a much earlier answer. That it did not do so was owing to purely accidental circumstances which I very much regret.

In that letter Mr. Culverwell criticises my treatment of Boltzmann's familiar proposition concerning the properties of the H function on the following grounds:—

(1) The choice of the generalised coordinates. In investigating the circumstances of a collision or an encounter between two systems of molecules of m and n degrees of freedom respectively, he sees a difficulty in my choice of the coordinates as $Q_1, Q_2 \ . \ . \ . \ Q_m, q_1, q_2 \ . \ . \ q_n$, where ($q_n = a$) determines a collision, or encounter. But supposing the requisite number of degrees of freedom to be secured, the choice of the independent variables is surely quite optional. I had myself assumed this as self-evident, perhaps too hastily, but at any rate Mr. G. H. Bryan has placed this proposition beyond doubt, in the exhaustive report submitted by him to the British Association last August. Take for example sets of plane circular disks moving amongst each other in their own plane; here each pair of disks constitutes a material system, whose position is completely determined (assuming the orientation of each separate disk to be indifferent) by the following four variables, viz. the two coordinates of the centre of one disk of the pair, the distance ρ between their centres, and the inclination of that distance to a line fixed in the plane; this third variable ρ is the q_n of my proposition.

(2) Mr. Culverwell objects that the general Boltzmann proposition $\left(\frac{dH}{dt}\right.$, always negative unless $\left.Ff = F'f'\right)$, or H a minimum for one, and one distribution only, cannot be true, because if a system were started from any initial configuration (P, Q), and after the time t arrived at the configuration (p, q) and the definite integral H were evaluated in these two configurations, the proposition asserts that the second H must be less than the first H, or $H_t < H_o$, whence it would follow by the same proposition that if at the end of the time t each velocity component were reversed, the H_{2t} must be less than H_t, and this, doubtless, I do assert. But Mr. Culverwell maintains that such an assertion is obviously untrue because at the end of the second interval t the system has returned to its *original* condition, and therefore H_{2t} must be the same as H_o, and to this proposition I demur.

Doubtless when a material system in a field of any conservative forces is started from any initial position and velocities, arrives after a time t at another position and with other velocities, and here has each velocity reversed, it is true that at the end of the next interval t it will be in its initial position, with each velocity component reversed; but it remains to be proved, and cannot be asserted *à priori*, that the H_{2t} is equal to H_o, and the only proposition available for the investigation is this very proposition of Boltzmann's, which proves that H_{2t} will be less than H_t, and therefore less than H_o.

Finally, Mr. Culverwell inquires, somewhat despondently, if anyone will point out the use of the H function, and what is proved by it.

I have already said in my second edition, that the proposition is not of my invention, and therefore that I have no claim to answer this question with any authority, but to my own mind the proposition appears certainly to clear away one obvious difficulty. Without the aid of this proposition we are enabled to assert that if F (p, q) were a function of the coordinates and momenta of a molecule such that in the absence of encounters *with other molecules*, F remains constant for all time, then the form of F satisfying the condition $Ff = F'f'$ must render F (p, q) $dp\ dq$ a *permanent* law of distribution, and therefore if we can assert that F (p, q) must *of necessity* be of the form F (E) (E sum of potential and kinetic energy), then the ϵ^{-hE} law of distribution is certainly a permanent law (neglecting, *i.e.*, all but binary encounters); but in the absence of this proposition, we cannot assert that the $Ff = F'f'$ is *necessary* as well as sufficient, because we cannot insist upon the necessity of an exact compensation in the passage from the $p\ q$ to the $p'\ q'$ state, and conversely, taking place at *each separate* encounter. The H proposition, therefore, removes this element of uncertainty, and reduces the question to that of the F (E) restriction, because it proves that unless $Ff = F'f'$ for *each pair* of encountering molecules, H and therefore F and f must be a function of the time. As I have already asked for a disproportionate share of your space, I will not enter upon the question of the F (E) restriction now.

H. W. WATSON.

I DID not exactly, as Mr. Burbury suggests, question Boltzmann's minimum theorem, but only the pages thereon in Dr. Watson's "Kinetic Theory of Gases." Indeed, I said that though I had not seen Boltzmann's proof, I supposed it to be all right.

It appears from Mr. Burbury's letter that in order to prove the theorem, even for the simple case of perfectly hard and elastic spheres, some amount of assumption as to an average state having been already attained must first be made, and of course the *à priori* reasoning in my letter is not applicable to such a theorem. Mr. Burbury's letter is exactly the kind of letter I hoped to elicit, and if he can say what assumption in a generalised system will replace the assumption of equal distribution of velocities in different direction in a system of hard spheres, he will clear up the whole difficulty. Unfortunately, the case with which he deals is one in which the error-law is known from other considerations to be the only permanent state.

I observe that Mr. Bryan, in his British Association Report, quotes the oversight I pointed out in Dr. Watson's proof, without making any criticism on it.

EDWD. P. CULVERWELL.

Trinity College, Dublin, November 24.

The Alleged Absoluteness of Motions of Rotation.

PROF. GREENHILL, in his review of Mach's "Science of Mechanics" (NATURE, November 15), writes as if he disapproved of that author's not accepting "Newton's distinction between the relativity of motion of translation and the absoluteness of motion of rotation." He appears to think that Mach would have obtained more insight into this distinction from a study of Maxwell's "Matter and Motion." It might more truly be said that Maxwell would have profited by a perusal of Mach's book The latter finally refutes the paradox contained in Newton's statement, and supported by Maxwell, and by so doing renders a great service to Mechanical Science. He has disposed once and for all of "absolute rotation." It is high time that writers on Mechanics should revise the preliminaries of their science so as to state their results in terms of relative motion, whether of translation or rotation. This has been partially done by Maxwell, and a further step has now been taken by Mach. It is unfortunate that the reviewer in drawing attention to this part of the book should have preferred to stand by the prejudice he owes to Newton and Maxwell when he might have done something to hasten its abandonment.

A. E. H. LOVE.

St. John's College, Cambridge, November 20.

MACH says truly (p. 237) "that precisely the apparently simplest mechanical principles are of a very complicated character; that these principles are founded on uncompleted experiences, which can never be fully completed," &c.

The modern student of theoretical mechanics is in a dilemma;

either he must accept the complete idea of the relativity of all motion, of rotation as well as of translation, as professed by Milton, Mach, and Mr. Love; or else he must follow Newton, Maxwell, and the German writers Streintz and Lange (attacked by Mach in Appendix iv.), and distinguish between the relativity of the motion of translation and the absoluteness of rotation. Euler, it appears, was a waverer, and according to Lange never arrived at any settled and intelligible opinion upon the subject. The first theory appears more analogically complete, but introduces unnecessary complication at an early stage; and stronger arguments than those of Mach, and others that I have yet met with, will be required to convert me to their side of the question. A. G. GREENHILL.

November 26.

Science Teaching in Schools.

IN the discussion on the teaching of science, and in the schemes put forward for reorganising this teaching, mathematics has so far been left out of consideration.

At present mathematics is taught for its own educational value, which has been traditional since the time of Plato; only in modern times has its great practical value been recognised. The teaching in schools takes little account, however, of the applications of mathematics, and whatever Prof. Greenhill may say (in his review of Prof. Mach's excellent book), there is still wanting complete harmony between those two points of view; not perhaps in the higher branches of the subject and its applications, but certainly in school teaching.

Boys, and girls too, in public schools are taught the elements of mathematics as if all were expected to become mathematicians, and the practical side is kept out of view. In the modern, or science side, which has been introduced at many schools, one finds too often chiefly those boys who show no talent either for classics or mathematics. Many of these have made little or no progress in Euclid; they cannot grasp the altogether abstract notions and symbols of algebra, and they therefore never come near trigonometry. But they are expected to understand the elements of chemistry, mechanics and physics; and it is instructive to find that they very often do understand a good deal of what is taught under these headings.

Now none of these subjects can be accurately taught—and inaccurate teaching is worse than waste of time—without the introduction of mathematical reasoning. Here we are in a vicious circle: the boys are considered incapable of learning mathematics, and therefore mechanics and physics have to be taught without any more than the most elementary notions of geometry and algebra; hence not much progress can be made.

In my opinion the order of procedure might be reversed. Mathematics might be taught through experimental science. If the boys themselves make, as they should do, experiments where they perform actual measurements, they will learn there are certain laws connecting various quantities; they will see that such laws can be expressed in simple symbols, and they will thus grasp in the concrete form the meaning of a formula or an equation which in the abstract form of pure mathematics remained a mystery to them.

Mathematics could in this manner be made very much easier and more interesting to the majority of boys. Geometry can be treated to a very great extent experimentally by aid of geometrical drawing and a development of the Kindergarten methods; the abstract logic of Euclid can then follow, or it can be treated at the same time.

Trigonometry need not be at once as fully gone into as is generally done, but the definitions of sine, cosine, &c., as names for certain ratios, can be easily and early introduced and made use of at once in mechanics or physics. Here also special experiments may easily be devised where measurements of angles or lines are made, and lines and angles calculated.

To explain fully what I mean I should require a great deal of space; in fact it would be almost necessary to draw up a distinct syllabus for a course on the above lines, or to give at least a great number of examples.

At present I wish only to urge that, while many attempts are being made to improve science teaching, and with it technical education, mathematics should be included, and to express my opinion that this science also allows of experimental treatment.

November 19. O. HENRICI.

MR. CRUMP (*vide* p. 56) though adopting a critical form and tone, really endorses the grounds of my suggestion that the Science and Art Department should dissever itself by an age limit from school science. He is inclined to be especially severe upon the defects of the Government examinations because they are controlled by scientific men, and to excuse the proper school examining boards because they have—according to Mr. Crump—attempted to examine in science without any qualification to do so. But I fail to see why eminent scientific men should be expected to be experts in elementary science teaching, any more than distinguished *littérateurs*, in the art of teaching to read, and it seems to me—in spite of Mr. Crump's "absolute" denial—that examining boards, neither professedly literary nor scientific but professedly educational, are more to blame in following and abetting the Department's premium upon text-book cramming. The fact remains that the London Matriculate ignores practical teaching of any kind, and that the "practical chemistry" of the Locals and College of Preceptors is essentially the same test-tube analysis as the South Kensington examination. Anyone who knows the London Matriculation examination—witness Miss Heath's concluding remark—will appreciate the quiet humour of Mr. Crump's allusion to it as "awakening and developing the powers of observation and reasoning."

H. G. WELLS.

The Explosion of a Mixture of Acetylene and Oxygen.

WITH reference to your note in last week's NATURE, I may say that, whilst the thanks of chemists, and particularly of those whose duty it is to perform lecture-experiments, are due to Prof. Lothar Meyer for once more drawing attention to the dangerously explosive nature of mixtures of acetylene and oxygen, it may be assumed that the facts already known concerning acetylene account sufficiently well for the great violence of the explosion, and hence for the circumstance that the mixture will shatter even the open cylinder in which it is detonated. What M. Berthelot terms the molecular rapidity of the reaction, as distinguished from the rapidity of propagation, in the case of mixtures of acetylene and oxygen is very high. The heat of the reaction, too, is nearly five times as much as in the cases of electrolytic gas and of carbonic oxide, and more than twice as much as that of methane. It is slightly exceeded by that of ethylene, but, on the other hand, the theoretical temperature of the change with acetylene is enormously greater than in the case of any other explosive mixture of gases. The temperature, too, required to initiate the change is, as Prof. Lothar Meyer showed indirectly some ten years ago, much lower in the case of acetylene than in that of the other gaseous mixtures of which he speaks. All the conditions tend to make the duration of the reaction so nearly instantaneous that the initial pressure cannot be far removed from the theoretical pressure, and this is sufficient to smash a much stronger envelope than a glass cylinder, even if the "tamping" be nothing more than the air. Everything we know about acetylene combines to show that it is extremely "sensitive" as an explosive, and that in this respect, as in its destructive action, it resembles mercuric fulminate.

T. E. THORPE.

"Newth's Inorganic Chemistry."

THERE are one or two points in Mr. Pattison Muir's review, upon which I should like to be allowed to say a few words.

Criticising the general plan of the book he says:

"It seems to me that the method of the author is radically wrong. Descriptive statements of facts ought surely, neither to precede, nor to follow, but to accompany the reasoning on these facts whereby general principles are gained."

It is not easy to see how the *descriptive statements of facts*, and the *reasoning on these facts* are to be printed in a book at all, unless one either precedes or follows the other. I can only suppose that my reviewer means, that such theoretical and other considerations as I have included in part i., and have called "introductory outlines," should in his opinion not be collected together either at the beginning or at the end of the book, but should be sprinkled among the descriptive chapters. It seems to me that the plan I have adopted, besides being a more orderly arrangement, and one more convenient for reference, is also the one that best enables the student to study the subject in the way advocated by my reviewer; and in order to impress upon the student that the study of descriptive facts should *accompany* the study of the reasoning on these facts, he is directed to "slowly and carefully" read part i. *while he is studying the descriptive chapters.* I venture to think also, that this method tends far less to "perpetuate the vicious and unreal distinction between chemistry and chemical philosophy" than that of obliging the student to gain his information of facts from one book, and his knowledge of theory from another.

Commenting upon the fact that part ii. is devoted to the study of four typical elements, Mr. Muir says:

"But hydrogen, oxygen, nitrogen, and carbon are not treated as typical elements; they are not compared and contrasted with other elements."

This criticism is not true. Chapter ii. of part iii. is prefaced with a short general account of the elements oxygen, sulphur, selenium, tellurium, in which the typical element oxygen is compared and contrasted with its *confrères*. Chapter iii. is prefaced with a similar brief sketch of the elements nitrogen, phosphorus, arsenic, antimony, bismuth, wherein the typical element nitrogen is compared and contrasted with the others of the group; and similarly at the beginning of chapter ix. the typical element carbon is compared and contrasted with silicon, germanium, tin and lead.

My reviewer is good enough to say: "The descriptions in this book of the members of each group of elements seem to me to be exceedingly well done; many portions of the chapters treating of principles and theories . . . are admirable." And again, a few lines further on: "The purely descriptive portions of the work are often extremely good, as far as they go. The facts, or rather half-facts, are stated in a clear and orderly way."

I am a little curious to know what *half-facts* are; and whether if such things can be, it would be possible to state them "in a clear and orderly way." If my reviewer merely means that there are so many more facts known than I have stated, that roughly speaking it may be said that I have only described one half of the known facts, I can only reply that I have endeavoured to select "from the overwhelming burden of so-called facts" such as seemed to me to be most important for the student, and which could be conveniently included within the limits of a small text-book.

Mr. Muir finds fault with my book because he does not discover in it "some fair and fitly fashioned building," which he says "ought to rise on this broad superstructure." I regret that this objection has not been stated in rather more explicit terms; I have tried to understand it, but cannot—perhaps it is poetical. In ordinary language one does not speak of a building as rising upon a superstructure. In no text-book of chemistry with which I am acquainted, is any trace of such a phantom edifice to be found, and it is sincerely to be hoped, that when the Joshua appears, who by raising such a "fitly fashioned building" shall "rescue chemistry from the overwhelming burden of so-called facts beneath which the science is in danger of being buried," he will choose some more suitable vehicle for making his views known to the scientific world than that of an elementary text-book on inorganic chemistry.

G. S. NEWTH.

I STILL hold that Mr. Newth's method is radically wrong. I admit it is not easy to make the descriptive statements of chemical facts accompany the reasoning on these facts; but although not easy it can be done.

As regards Mr. Newth's treatment of the four typical elements, hydrogen, oxygen, nitrogen, and carbon, I can only repeat that the comparisons and contrasts made between these elements and those of which they are representative are, in my opinion, worth very little.

I cannot enter into a discussion of the meaning of the term "half-fact"; but I can assure Mr. Newth that in saying he had stated "half-facts in a clear and orderly way," I did not mean to say he had stated about half of the known facts and omitted the rest. It is characteristic of half-facts that they are very amenable to clear and orderly arrangement.

When I spoke of "some fair and fitly fashioned building" rising "on this broad superstructure," of course I should have written "broad substructure." I am much obliged to Mr. Newth for pointing out this stupid slip.

I thought Joshua was more concerned with demolishing towns than with raising buildings; but my Hebrew history is a little rusty.

M. M. PATTISON MUIR.

Cambridge, Nov. 21.

Singing Water-Pipes.

AT Oxford, Prof. Osborne Reynolds showed an interesting case of sound in water. There is another familiar effect, of which he has probably given the reason, but it does not seem to be commonly known.

A little while back there was a clear steady note carried through my house by the water-pipes, a note of the middle octave of the quality of an organ diapason pipe. When the source was found, it was easy to change the note through the octave. The music arose as often as the scullery tap was turned on, and lasted so long as the water was running. The tap was worn, and the flow of water kept up a rapid tapping of the loose part, just as in Trevelyan's Rocker.

The singing is sometimes heard after a tap is turned off. This happens because the ball-tap of a cistern has thus been left running.

W. B. CROFT.

Winchester College, November 26.

An Aurora on November 23.

STEPPING out of doors to-night, November 23, at 7.30, I was surprised to see the whole northern sky filled with luminous mist, so clear that our shadows were dimly observed on the shining surface of the wet highway. There were few tremulous motions, but the light clouds advanced southwards in great patches. For a while the planet Jupiter shone to the east of the luminous haze. Then the mist passed over Jupiter, who shone, however, with nearly its wonted splendour until a great detached belt hung between Jupiter and Pleiades, over to the south-west horizon.

The Milky Way became obscured as the haze passed right over our heads. By eight o'clock the detached luminous belt, which was not uniform, but in patches, had reached the planet Mars. Neither was the light in the north uniform, but here and there were clear spaces. By 8.10 the aurora was much dimmer. By 8.30 there was no luminosity except in the north, between the Great Bear and the horizon.

J. SHAW.

Tynron, Dumfriesshire.

A Snake "Playing 'Possum."

A PUFFING adder, *Heterodon platyrhinus*, caught by the writer in May 1894, exhibited a most curious instance of feigned death which may be worthy of record.

The snake when discovered at first tried to escape, but on being captured it turned on itself with mouth wide open, head thrown back sharply, and tongue limp and protruding. The mouth remained open thus to its fullest extent, while the head and upper part of the body threshed violently from side to side for a few times, and then his snakeship rolled over on his back, and after a few convulsive movements became apparently lifeless. The body was then quite limp, and remained in whatever position it was placed, providing the snake was on his back, but when turned over in the proper position, he immediately rolled back by an almost imperceptible muscular contraction. When struck lightly, pinched or held up by the tail, there was very slight resistance. He continued in this state for about half an hour, when no attention having been paid to him, he resumed his normal position. A little teasing caused a repetition of this performance a number of times afterwards, and it did not vary in any essential particular. It would be interesting to know whether this is a ruse common to individuals of this species, and if so whether it is confined to them alone.

L. C. JONES.

The Soaking of Seeds.

IN reply to Mr. Alfred W. Bennett's inquiry as to the soaking of seeds in milk before sowing, it may interest him to learn that in book iii. section v. of his "Deipnosophists," Theophrastus is quoted by Athenæus as saying that "cucumbers contain a more agreeable and wholesome juice if the seed be steeped in milk or mead before it is sown," and that "plants come up quicker if they are steeped in water or milk before they are put in the ground."

P. C. GLUBB.

Pendean, Liskeard, November 13.

HISTORY OF ENCKE'S COMET.

HISTORICALLY, Encke's comet, which has recently come into view again, stands next in interest to Halley's. The history of the latter can be carried back much farther than that of any other comet. It was indeed conjectured that the one (the first telescopically discovered comet, by Kirch) which made so near an approach to the sun in 1680, and in reference to which Newton first applied his principle of universal gravitation to the motions of these bodies, was identical with comets seen at intervals of about 575 years before, and Gibbon (not exactly an astronomical authority, who recommends others to study Newton and Halley on the question) devotes a section of his forty-third chapter to the supposed history of these early appearances (two of them in mythical times), concluding with the remark that the calculations with regard to it might perhaps in the year 2355 "be verified by the astronomers of some future capital in the Siberian or American wilderness," little thinking how many splendid telescopes would be employed on the study of the heavens in the "far west," before a century had elapsed from his own death. There was then, in 1794, no observatory on any part of the American continent. But it is now known that the period of the comet of 1680 amounts not only to hundreds, but to thousands of years; and one of the supposed previous appearances, that in the reign of the Emperor Justinian, was in all probability a return of the smaller or less conspicuous comet which appeared in 1682, and at the next return in 1758–9 acquired the name of Halley's comet, because that eminent astronomer had confidently predicted its return at that date, calling upon posterity to notice that the prediction had been made by an Englishman. He recognised its identity with comets observed in 1531 and 1607, by a comparison of the orbits calculated for each, and considered from the similarity of period, that the fine comet of 1456 was also probably an earlier appearance of the same. Later investigations, and the accessibility of Chinese records, have shown since his time that successive appearances of this body can be traced with very great probability to a date before the Christian era, our distinguished countryman, Dr. Hind, having taken a leading part in these calculations.

Of the subsequent observations of this comet in 1835, this is not the place to speak, nor of the full expectation astronomers then living will entertain of seeing it again in 1910, and applying the new methods of analysis to it, thereby obtaining information respecting its constitution, which was beyond the wildest flights of imagination at its last appearance. For our present subject is a comet which acquired the name by which it is now universally known as a fitting meed of honour to an astronomer who worthily presided over the then new observatory at Berlin within our own recollection. Many comets have since that time returned according to prediction; but when Encke announced that the small one discovered by Pons at Marseilles on November 26, 1818, was identical with the discovery of Méchain in 1786, of Miss Herschel in 1795, and of Thulis in 1805, no predicted return of any comet but Halley's had ever taken place, though two predictions had been made, by himself and by Bessel respectively, of the returns of comets observed in 1812 and 1815, which duly came to pass in 1883 and 1887, the periods of these being nearly as long as that of Halley's. The remarkable point about Encke's comet was the extreme shortness of its period, amounting only to 1212 days, or three years and about four months. It was therefore concluded that it would reappear in 1822; true to prediction it did then appear, but from its situation in the heavens was visible only in the southern hemisphere, which then possessed only *one* observatory, that established (but which has long ceased to exist) by Sir Thomas Brisbane at Paramatta, New South Wales, where the comet was rediscovered by Rümker on June 2. The next appearance took place in the autumn of 1825, when the comet was observed in this hemisphere, and since that time it has never failed to be observed at the calculated epochs. Encke did not desert it after he had determined its period in 1819, but, following up its motions with accuracy, was led to notice a remarkable continuous shortening of the period by a fraction of a day at each return. The question had before his time been started whether a medium might be diffused through the solar system which, though insufficient to affect the motions of the planets, would produce appreciable effects upon those of comets, composed as they must be of matter in a state of great rarity. Here was a case which seemed to settle the question in the affirmative. Encke's calculations showing that the diminution in the observed length of the period was such as might well be caused by the action of such a resisting medium checking the onward motion of the comet, which would bring it a little nearer to the sun at each return, and thus shorten both the orbit of revolution and the period of time in which it was accomplished. The difficulty remained how to explain the fact that no such effect was perceptible in the motions of any other comet; a difficulty which the lapse of time has not removed, for though in one other case (that of a comet known as Winnecke's) a similar effect was for a while thought to be noticed, further investigation showed that this view could not be sustained. Encke, however, to the end of his life (he died in 1865) was able to trace the above continuous effect in the motion of his own comet, the period of which was then 1210·2 days, or 1·6 days shorter than it had been in 1819. But, strangely enough, soon afterwards, the amount of retardation was reduced by about one half, at which it has remained from 1868 to the present time. Must the resisting-medium theory be modified, or must it be altogether abandoned and some other cause be sought for the retardation in question? Prof. Young suggests a regularly-recurring encounter with a cloud of meteoric matter.

When nearest the sun, Encke's comet is at very nearly the same distance from him as the planet Mercury. When farthest from him, it is in the zone of small planets (nearly four hundred of which are now known), revolving between the orbits of Mars and Jupiter. May the attraction of some of these have something to do with the effect above referred to? Small as is the mass of most of the tiny bodies in question, it is possible that at certain times some of them may act together and produce a cumulative and appreciable effect. Of great value to astronomy has been the position of Encke's comet at the other extremity of its orbit, in perihelion. Before its discovery, the mass of Mercury had been rather a matter of conjectural inference than of actual calculation, that planet having no satellite the motions of which would be affected by its attraction. But at certain returns, the comet of which we are treating, made very near approaches to the planet, and the effects produced on these occasions have enabled astronomers to obtain determinations of the mass of the planet as accurate, or nearly so, as those determined for the larger planets which have satellites. The first of these near approaches since the comet's discovery took place in 1835; the last at the most recent return, in 1891.

We now come to the physical appearance of Encke's comet. It has on some occasions, when nearest the Earth, been just visible to the naked eye, particularly in the autumns of 1828 and 1848. After Miss Herschel had detected it (supposed to be a new comet), at its return in 1795, her brother, Sir William Herschel, observed it on November 8, and noticed it the following day pass centrally over a star of the twelfth magnitude without obscuring it, whence he concluded that the comet "is evidently nothing but what may be called a collection of vapours." Maskelyne, who observed it at

Greenwich a few nights afterwards (Bode had in the meantime, in company with an amateur astronomical friend, detected it at Berlin on November 11, four days after Miss Herschel's discovery at Slough), contested this view on the ground that the nucleus might be situated not in the apparent centre of the comet. And this indeed would seem to be the case; the general appearance of the comet, when seen under the most favourable circumstances, being that of a slightly oval vaporous mass, with a small ill-defined nucleus eccentrically situated within the coma. In 1848, towards the end of September, a faint brush of light was noticed by Prof. Bode, extending from the more condensed part of this towards the sun; and a few weeks afterwards a tail, between one and two degrees in length, was seen on the other side, *i.e.* the normal position of a comet's tail. Late in the month of November in the same year, it may be remarked, the comet made one of its very near approaches to Mercury, coming within the distance 0·038 of the Earth's mean distance from the sun, or about three and a half millions of miles. The return of 1871 was a noteworthy one in several respects; and particularly for the remarkable fan-like appearance which the coma presented in November and December.

The apparent contraction of a comet's bulk as it approaches the sun, and dilatation of it again when receding from him, which has been manifested in several of these bodies, has been especially marked in the case of Encke's, the visible diameter at perihelion being not equal to the twentieth part of what it is about the time when the comet first comes into view. The most probable cause of this would seem to be that suggested by Sir John Herschel, which would make it rather apparent than real, namely, that near the sun a part of the cometary matter becomes invisible by evaporation, just as a cloud of fog might be.

In 1871 the spectrum of this comet was examined by Prof. Young, and found to consist of three bright bands, of which the central one was the most prominent; they were somewhat sharply defined on the least refrangible side, whilst on the other they were diffused. "Of a continuous spectrum there was no trace, and the spectrum was the same from every part of the comet." But in 1881 a faint continuous spectrum was detected by Prof. Tacchini, so that the result of spectrum analysis applied to this comet would seem to be essentially the same as that obtained from the great majority of comets of which the light has been examined in this way.

At the last appearance of Encke's comet, in 1891, it was first seen by Prof. Barnard at the Lick Observatory in California, at the beginning of August, and passed its perihelion on October 18. At the present return it was detected at the Nice Observatory on October 31, in the constellation Pegasus; and Dr. Max Wolf found it registered on a photographic plate taken by him the same evening at Heidelberg. As on several previous occasions, its ephemeris has been calculated by Dr. Backlund, of Pulkowa; and it is matter of regret to notice his accompanying announcement that this is the last occasion on which he will be able to undertake it. The earlier portion of this ephemeris was given in NATURE last week.

W. T. LYNN.

PROGRESS OF THE CATARACT CONSTRUCTION COMPANY'S WORKS AT NIAGARA.

THE general scheme of the Niagara Falls Power Company has already been described in these columns (NATURE, vol. xlix. p. 482). We understand that the great power house is now complete, and the foundations ready for the three great 5000-horse power dynamos which have been constructed by the Westinghouse Company. The turbines and vertical shafts up to the floor of the power house have long been in place, and the dynamos may now be shipped any day. They have already been revolved in the shops at full speed. Our readers will remember that there is no gearing. The dynamos are on a vertical shaft, and the revolving fields are external to the armature, forming a sort of bell-cover to it, with the poles pointing radially inwards. This was the only design which Prof. Forbes could make to fulfil the requirements of the turbine designers as to maximum weight and minimum fly-wheel effect to be allowed. It gives a splendid mechanical construction, as the revolving pole-pieces and coils are retained in place against the centrifugal forces by the nickel-steel ring which forms the yoke.

The first place to be supplied with current is the aluminium works of the Pittsburg Reduction Company. To convert the two-phase, 2000 volt alternating current into a continuous current of 160 volts at these works, 2500 feet from the power house, transformers are there used, and the low pressure alternating current in two phases is supplied to commutating machines. This is a new departure of great interest, as no machines of this class have been previously built except for experimental purposes. They are each of 500-horse power, and are continuous current machines with four rings attached to four bars of the commutator. The alternating current is supplied by brushes rubbing on these rings, and it drives the machine as a motor. The continuous current is taken from the commutator by brushes in the ordinary way. All this machinery was made for the Cataract Construction Company by the General Electric Company, which is far the largest electrical concern in the United States. The machinery was tried in September, and it seems to work admirably. Four of these machines, with eight transformers, equal to 2000-horse power, are being put down to begin with.

The next place to be supplied is the Carborundum Company, which makes a substitute for emery, much harder, being composed of carbon and silicon raised to a high temperature in an electric furnace. They begin with 1000-horse power, and their factory is making good progress.

After that the Buffalo transmission will go on, but the selling of power in the neighbourhood is more profitable than at a distance; and many of the manufacturers, who have been holding back for two years to see how the tariff was to be settled, will now start factories, and some of them will settle at Niagara Falls to get the cheap power.

The transformer house, for raising the electric pressure from 2000 to 10,000 or 20,000 volts, is on the side of the canal opposite the power house, and these are connected by a massive stone bridge, with a covered way for carrying the cables. The concrete subway starts from the transformer house, and is at present to be used for supplying the first customers on the Company's lands.

Everything looks most promising at present, and as to the electrical works, everything indicates that any other general scheme than the one adopted would have been vastly inferior. Especially is low frequency proving itself invaluable. The continuous current could not have been got for the aluminium works without it, the motors will be far more satisfactory, and the safety and economy of the line is far higher. It was once objected that transformers could not be cheap or efficient at the low frequency proposed. Prof. Forbes held, however, that large sizes could be got even with low frequency at half the cost and at higher efficiency than anything that had been done on a small scale. This statement was based upon his own designs; and now it is entirely supported by all the manufacturers who have made designs for the work.

THE NILE RESERVOIR.

AN official memorandum upon the proposed modifications in the Assuan dam project has been drawn up by Mr. W. E. Garstin, C.M.G., Under-Secretary of State in the Egyptian Ministry of Public Works, and is published in Tuesday's *Times*. It will be remembered that an account of the schemes for the irrigation of Egypt was given in these columns a few months ago (vol. l. p. 80).

Several arguments have been brought against the Assuan cataract as the site for the dam. The first is that this site is not the only possible one to be found north of Wadi Halfa. The second, and, at first sight, the strongest, argument against the proposal is that it is impossible to lay down as an axiom that the Assuan cataract site is the only feasible one for a dam, while the river valley south of Wadi Halfa has been unexplored and unsurveyed.

Mr. Garstin criticises the arguments, and shows that the project proposed best meets the case. In this opinion he is supported by the English and Italian members of the Technical Commission—Sir Benjamin Baker and Signor Torricelli—who reported that there is only one safe site for a dam between Cairo and Wady Halfa, namely, the Assuan cataract. Subjoined is Mr. Garstin's description of the scheme. The careful consideration which has been given to the matter reflects great credit upon the Egyptian Government. Science is to be congratulated upon the action that has been taken; for the benefits that will accrue to it from the investigations which it is proposed to carry out over the whole of Nubia will be of the highest importance.

The Council of Ministers on June 3, 1894, approved in principle of the proposed dam and reservoir at the Assuan cataract, and directed the Ministry of Finance, when preparing the Budget for 1895, to occupy itself with the question of obtaining the funds necessary for the execution of this work.

The project, as then submitted to the Government, consisted of a dam with its crest at R.L. 114·00, which height would have enabled wa'er to be stored in sufficient quantity for the requirements of Middle and Lower Egypt; in other words, for the whole country lying to the north of Assyut.

Most unfortunately the construction of this dam would have necessitated the submersion for some six months every year of the celebrated Philæ temples, as well as of a considerable number of Nubian monuments, which, although less known than those of Philæ, are of great importance to all those interested in the history of ancient Egypt.

The archæological societies of Europe, upon hearing of this proposal, protested against it in the strongest terms, and begged the Egyptian Government to reconsider its decision, and to endeavour to find some alternative scheme by which the country might reap the advantages to be derived from a storage reservoir, without sacrificing the interests of science and archæology.

The Ministry of Public Works, recognising that these protests were founded upon reasons so strong as to command respect, reconsidered the whole matter in detail, and endeavoured to find such modifications of the original scheme as might reconcile the interests of Egypt and of science.

The result of its studies is the modified project which has now been submitted to the Egyptian Government.

* * * *

The modified scheme as at present submitted is of the nature of a compromise; it is hoped that it will satisfy the scientific world, while, at the same time, it will further the interests of this country.

It is now proposed to build a dam at Assuan with its crest at R.L. 106·00, or eight metres (26 ft.) lower than that of the original project. This work will of necessity store very much less water than the high-level dam would have done. At the same time a reservoir of this height will supply sufficient water for the wants of either Middle or Lower Egypt separately, although not for their combined areas.

This will mean that the reclamation of the country will proceed more slowly than was at first proposed; and when in course of time the country to the south has been explored a second dam can be made which will store sufficient water for the needs of the rest of Egypt.

This proposal is no new one, but has been fully discussed and estimated for in Mr. Willcocks's report upon the different sites.

The great advantage to be derived from carrying out the work in the above manner is that it will only submerge portions of the Philæ island, while it will leave the rest of the Nubian monuments untouched. A reference to Mr. Somers Clarke's note upon these latter will show that their levels are all well above that of the highest water surface in the modified project as now submitted.

As regards the Philæ temples, the main buildings will be above high-water level altogether. It is true that the South Quay wall, and some of the smaller temples, would be submerged if left unprotected. It will, however, be possible, by the construction of a low water-tight wall, or by other means, to so arrange for their protection that no damage will be done to them by the water.

To a certain extent the artistic beauty of the group will be impaired, but in a land so full of interesting relics as is Egypt, it is unfortunately impossible to carry out any great public work without in some degree interfering with some one or other of these. The only thing to be done is to try and minimise this interference as far as is possible, and in the present case the Ministry of Public Works thinks that it has succeeded in so doing.

As regards the details of the protection works to be carried out upon the Philæ island this Ministry will consult the scientific societies upon every point, and will endeavour, as far as lies in its power, to meet their wishes in the matter.

In order to still further minimise any possible loss to science which might ensue from the construction of the reservoir, it is proposed to carry out an archæological and scientific investigation of the whole of Nubia.

The English societies very rightly impressed the necessity of this work upon the Egyptian Government. The latter, although both willing and anxious to carry it out, found it impossible to do so, owing to the necessary funds not being available. If, however, the reservoir be made this difficulty at once disappears, as the cost of the above investigation will be added to the estimate of the dam itself.

The Public Works Department has been directed to put in hand as much of the work as lies within its scope and power during the ensuing winter season. Topographical surveys will be made and plans prepared; the true bearings of the temples will be fixed and the preliminary plans of all sites completed.

This portion of the work being done, the Egyptian Government will ask the European scientific societies to depute certain of their members to come to Egypt and complete the work.

In this manner it is hoped that a record and a knowledge will be obtained of this most interesting country which will be worthy of the present age, and which should be of the greatest value to the scientific world in the future.

NOTES.

WHERE the good of science is concerned, the Goldsmiths' Company is generally among the leading benefactors. With characteristic generosity, the Company has decided to make a grant of one thousand pounds for the purpose of prosecuting research work in connection with the anti-toxin treatment of diphtheria, and in aid of the manufacture of the serum. At the request of the Company, the Laboratories' Committee of the Royal College of Physicians and Surgeons have undertaken the administration of the grant.

REUTER'S correspondent at Rome reports that at a quarter past six on the morning of Tuesday, November 27, an earthquake occurred at Brescia, in Lombardy. The shock was followed by subterranean rumblings. A similar, though less violent, movement was felt at Bologna at nine minutes past six. Five minutes earlier a sharp disturbance occurred at Vienna, lasting four seconds. It was followed almost immediately by a second slighter shock of two seconds' duration. Shocks were experienced about the same time at Domodossola, Mantua, Pavia, Parma, and Bergamo, while at Rome the seismic instruments gave evidence of disturbance.

THE Société Internationale des Électriciens established a central laboratory at Paris about seven years ago. The principal object of the laboratory was the preservation of electrical standards, and to afford practical electricians an opportunity for testing their various instruments. It is evident that such a laboratory offers special advantages for the investigation of questions belonging to the science and industry of electricity. These facilities have been to some extent utilised; but in order to increase the usefulness of the institution, the Society has added to it a School of Applied Electricity. This school, which will be opened on December 3, has been constructed on a plot of land granted by the city of Paris, the funds for the building having been raised by private subscription. Purely practical instruction will be given at the school. There will be two chief courses, one dealing with the industrial applications of electricity, and the other with electrometry. It is hoped that the school will be a training ground for higher work in the Central Laboratory, to which it is attached.

A RUSSIAN ethnographic exhibition will be held next year in the Champ de Mars, Paris.

THE University of Chicago is establishing a special department of botany, with Prof. J. M. Coulter at its head.

IT is announced that the printing of the important and laborious "Index Kewensis" will probably be completed about Midsummer 1895.

THE death has recently occurred of Dr. L. Schwarz, the Director of Dorpat Observatory, and the Professor of Astronomy in the University there.

THE resolutions passed by Convocation at Oxford, last summer, in favour of conferring degrees upon persons who have pursued a course of special study or research in the University, were submitted to a Congregation on Tuesday, and, after some discussion, the preamble was carried by a majority of sixty-nine votes.

A DALZIEL telegram from Halifax, Nova Scotia, dated November 27, says: "It is reported that the steamer *Falcon*, of the Peary Arctic Exploration Expedition, was wrecked on the Virgin rocks, some distance off the southern coast of Greenland in October, and that all on board perished."

THE Royal Botanical Society of Belgium has established a Committee of Vegetable Pathology, holding its sittings in the Botanic Garden at Brussels, for the purpose of affording information to nurserymen, horticulturists, and arboriculturists, respecting the diseases which attack plants, and the best mode of combating them.

IN January last, attention was drawn to the fact that a sale of seven lions had taken place at the gardens of the Royal Zoological Society of Ireland, of which number six were born in Ireland. A further batch of five cubs, all males, has recently been disposed of by the Council, after a protracted correspondence. The total exchange value for these twelve lions exceeds, we understand, £500.

AGRICULTURAL Associations seem to be waking up to the necessity for the scientific investigation of diseases and pests affecting crops. One of the resolutions passed at a largely-attended conference of agricultural societies of New Zealand held during the past summer, was—"That the services of a first-class entomologist be obtained by Government, who shall give his whole time to an examination of insect pests, with a view to their destruction." It was also resolved to request the Government to get expert opinions as to the best method of exterminating the grub in corn and grass crops.

THE promotion of an intellectual observance of Sunday is the object of the Sunday Society. At present the Society numbers among its chief aims the opening of the Natural History Museum and the South Kensington Museum on Sundays, so that the scientific collections of the nation shall enlighten a wider public. In furtherance of the general principle involved, a number of special sermons will be delivered next Sunday, this being the Society's third annual Museum Sunday; and several science and art collections will be open to members of the Society.

NEAR Dunkeld Cathedral, in the Duke of Athole's grounds, are two of the original five larch trees said to be the first introduced into this country. They were planted in 1738, and in the year 1888 they were measured with the following results:

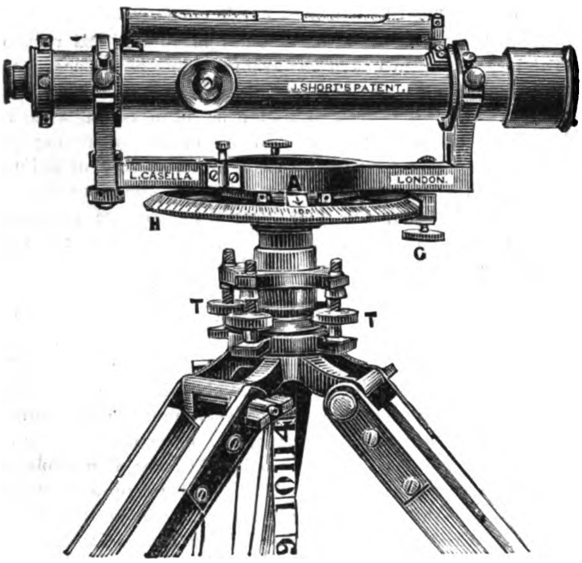
Height	102 ft. 4 in.
Circumference:	
3 ft. from ground ...	17 ft. 2 in.
5 ft. ,, ,, ...	15 ft. 1 in.
17 ft. ,, ,, ...	12 ft. 10½ in.
51 ft. ,, ,, ...	8 ft. 8 in.
68 ft. ,, ,, ...	6 ft. 1 in.

MR. WALTER B. HARRIS gave an account of his recent journey to Tafilet, at the last meeting of the Royal Geographical Society. He left Morocco city on November 1, 1893, in disguise, and crossed the Atlas at an elevation of a little over 8000 feet. In connection with this, it is worth noting that the *Bulletin* of the Paris Geographical Society (vol. xv. p. 199) contains a description, by M. Gabriel Delbrel, of a visit he paid to Tafilet last year.

DR. KARL KARSTENS, of Kiel, has made a critical revision of the various estimates of the average depth of the oceans, as arrived at by the methods of different calculators. These methods he classes as of three kinds: that of measuring areas by the planimeter on a contoured map, that of calculating the areas of successive profiles drawn at intervals of 5° of latitude apart, and that of taking the mean depth of the soundings in definite small areas, and combining these to give the mean depth of the whole. Murray and Penck had made calculations by variations of the first method, and got out the mean depth of the oceans as 3797 metres (2074 fathoms) and 3650 metres (1995 fathoms) respectively; Heiderich, by the second method, got 3438 metres (1881 fathoms); and Krümmel, by the third method, gave the figure 3320 metres (1815 fathoms). Since Krümmel's calculations were made in 1886, his student Karstens has gone over them, taking advantage of the very numerous additional soundings which have been made, and he comes to the conclusion that the average depth of the oceans as a whole is 3496 metres, or 1909 fathoms. The maximum probable value was 3632, and the minimum 3377 metres. The mean depth of the Pacific Ocean is given as 3829, of the Indian Ocean 3593, and of the Atlantic 3160 metres.

HERR P. DINSE published the first part of a discussion of the geographical characteristics of fjords in a recent number of the *Zeitschrift* of the Berlin Geographical Society (vol. xxix. p. 189). This instalment deals with the morphology of fjord-riven coasts, a subsequent paper being intended to treat of the theory of the origin of fjords. The author distinguishes between *fjords* or inlets running into steep coasts, and sometimes branching, including one or more basins deeper than the sea immediately outside, and *fjord-channels* or sounds which are similar but open at both ends, and *fjord-lakes* which are similar but closed at both ends, and separated from the sea. A farther distinction is drawn between the different kinds of inlet which superficially resemble fjords, the most contrasted in submarine configuration being the *rias* of Spain and other coasts, in which the depth of the water gradually increases from the head until it merges in the general deepening of the sea outside. The inlets of the south-west of Ireland are examples of this type, contrasting with the characteristic fjords of the north-west of Ireland, the west of Scotland, and Norway. The greater part of the paper is occupied by an account of the distribution of the varieties of fjord-coasts in different parts of the world, and the generalisation is made that there are none of those coast-features outside the limits of lands which bear signs of recent glaciation. Herr Dinse has made a complete discussion of the principal dimensions and the exact configuration of eighty-three fjords in all parts of the world, taking his data from the largest-scale sea-charts available for each region, and these figures are printed as an appendix. The paper is illustrated by a few contoured maps of fjords, and by profiles showing their longitudinal and transverse sections.

THE Gradient-Telemeter Level, of which we give an illustration, should be of service to civil engineers and surveyors. Its novelty consists in the absence of a vertical circle, while a circle tilted out of the horizontal plane takes the place of the horizontal circle in an ordinary theodolite. So constructed, the instrument can be used to obtain linear distances, gradients, and differences in level of objects without the use of land-chain or tape. The circle is divided into natural tangents instead of degrees. When the reading is zero, the telescope is horizontal, but by rotating the circle, the telescope is inclined to the horizontal line, and the inclination is indicated by the pointer to the circle. As an example of the use of the instrument,



suppose the whole of the levelling staff to be below the horizontal line of sight. Setting the circle for a gradient of one in twenty-five, let the reading of the staff be 13·86. Now set the circle so that the index points to a gradient of one in twenty, and let the reading be 8·45. The difference between these two readings is 5·41, and, eliminating the decimal point, the number obtained—541—is the horizontal distance in feet between the instrument and the staff, without any further calculation. Other pairs of gradients may be used, and the difference of their staff-readings gives the linear horizontal distance. The instrument thus greatly simplifies many surveying operations.

A COLLECTION of valuable notes on the aborigines of various parts of Australia is given in the November *Journal* of the Anthropological Institute. The notes, which take the form of answers to questions on the manners, customs, religions, superstitions, &c., of the native tribes of Australia, have been collected by Dr. E. C. Stirling. The natives are divided into innumerable tribes, and different customs prevail every two hundred miles or so. Arithmetic is beyond their comprehension. Most of the tribes appear to have distinctive names for one and two, but for three they say two and one; for four, they say two and two; and for five, two two and one. The fingers are used in counting, but numbers beyond five are very seldom used. Numbers greater than ten are usually described as "plenty" and "many," and explained by opening and closing the hands several times. The tribes have a very limited knowledge of the measurement of time. They tell the time of day by the sun, and speak of the different times of the position of the sun. They reckon by so many moons, and determine the year by the seasons; but they have no knowledge of the constellations, nor have they any names for the months, or moons, as they call them, or any recognised beginning of the year, nor artificial timekeeper of the nature of sun-dials, though the lengths of the shadows of trees is used by some tribes to determine the time of day. The heavenly bodies are not worshipped, neither are any ceremonies performed at the new moon, sunrise, sunset, the solstices, equinoxes, &c. The Milky Way is supposed to be the largest creek or river. A fresh sun is believed to shine every day, and the phases of the moon are explained by the prevailing course of the wind and prevailing quarter of the rain. Eclipses, rain, thunder, lightning, rainbows, wind, and Aurora Australis are supposed to be the work of evil spirits. Many other beliefs are described in the notes, which will be read with great interest by every student of anthropology and folk-lore.

THE mutual alterations effected between an invading igneous mass and the rock which it invades, have long been the subject of much study and speculation. An interesting case, presenting some exceptional features, has recently been described by Prof. Cole (*Trans. Roy. Dublin Soc.* vol. v. (n.s.) No. 5). On the coast of Co. Down, the Ordovician strata are cut by numerous basic dykes. In some cases, material of more acid composition has intruded at a later date, and, forcing its way along the same lines of weakness as the earlier basic material, has produced "compound" dykes. It is one such compound dyke, at Glasdrumman, consisting of basaltic andesite rifted lengthwise by later eurite, that Prof. Cole describes in detail. The new-comer has re-melted the more easily fusible andesite, and the two magmas have mixed along the contact. Various stages of mixture are described, but the most interesting facts are those concerning the large crystals of quartz and felspar which abound in the marginal portions of the eurite. These crystals have evidently consolidated under other, and earlier, conditions than the main mass of the rock, since portions of the eurite-matrix have eaten their way into them before solidifying. But crystals undoubtedly so corroded are also found in the andesite, into which they must have floated from the eurite. The presence in a rock of crystals of evident foreign origin is no new thing, but hitherto it has, in all such cases, been either shown or assumed that they were caught up by the rock in which they are found from some other into which it had intruded; whereas, here, it is the invading eurite that has parted with its crystals for the benefit of its host. Thus the common dictum, that "an enclosed block must be older than the rock immediately enclosing it," is apparently controverted; yet, since consolidation is the datum from which age is measured, it becomes a decidedly nice point in geological nomenclature whether a partially re-fused rock can be allowed to pass as entirely older than the rock which has re-melted it.

SOME interesting particulars concerning "aventurine glass," one of the most curious products of the world-renowned glass-works at Murano, near Venice, are given in the current number of the *American Journal of Science*, by Mr. Henry S. Washington. Its name is derived from its supposed discovery "by chance," some brass filings having been dropped accidentally into a pot of molten glass. After the late Dr. Salviati's revival of the glass industry at Murano it was rediscovered, but the present process is a trade secret. The best glass is of a copper-brown colour, and transparent to translucent in thin flakes, showing on the edges a pale brown colour. It is filled with innumerable small flakes and spangles of a slightly brownish yellow colour and brilliant metallic lustre, consisting of crystallised copper. Under the microscope the glass shows a porphyritic structure, the ground-mass being composed of a perfectly clear and colourless glass basis. The crystallised portions consist of large phenocrysts, small phenocrysts, and microlites. The former range in diameter from 0·05 to 0·12 mm., are tubular and extremely thin, the thickness scarcely exceeding 0·002 mm., and are perfectly opaque notwithstanding their excessive tenuity. Most of them are hexagonal in outline, the hexagons being of almost ideal symmetry; but equilateral triangles, which occasionally show truncated angles, also occur. The smaller phenocrysts are much more diverse in crystalline form, and may be generally grouped in one of three divisions: cubo-octahedral forms, octahedra, and twins. They occur in portions of the glass free from the larger phenocrysts, but filled with abundant microlites, from which they are usually separated by a clear zone. The copper has evidently crystallised out from solution in the molten glass exactly like a salt from water, following Lehmann's laws of crystal growth in solutions. Mr. Washington is of the opinion that the glass is produced by melting together glass, cuprous oxide, and some reducing agent, such as siderite; and that FeO is in this case the reducing agent is shown by the greenish colour of the imperfect glass, which is not the blue green of copper, but the yellow green of ferrous glass, and perhaps due to too large a quantity of reducing agent.

AT the last meeting of the French Physical Society, MM. Cailletet and Colardeau read a very interesting paper on the condensation of the gases produced by electrolysis on electrodes formed of metals of the platinum group. It is well known that when acidulated water is electrolysed by means of platinum electrodes that, on removing the battery and connecting the electrodes, a current is obtained in the opposite direction to the original current used to perform the electrolysis. This current, which only lasts for a short time, is explained by the recombination of the hydrogen and oxygen which coat the platinum electrodes. The authors, taking advantage of the well-known property of finely-divided platinum of occluding gas in large quantity, were led to use masses of finely-divided platinum contained in silk bags as electrodes, and in this way, using electrodes weighing six grms. each, a current was obtained, after disconnecting the battery, which continued for some time, and was of sufficient strength to ring an electric bell. By enclosing this form of the cell in a receiver, and compressing the air within the receiver, the following results were obtained:—With an additional pressure of one atmosphere, the E.M.F. immediately after charging was 1·8 volts, which fell regularly to zero when the cell was discharged. On increasing the pressure the character of the discharge-curve obtained entirely alters, and consists of three parts. (1) A portion in which the intensity of the discharge current rapidly diminishes. (2) A portion during which the current remains constant. This period occupies the major part of the time occupied in the discharge, and the E.M.F. at this time is about one volt. (3) A second period in which the current diminishes and finally becomes zero. The capacity of such an accumulator, the weight of the two electrodes being 1 kilogram, is, under a pressure of 580 atmospheres, 56 ampere-hours, while a current of 100 amperes can be obtained. To obtain the best possible result, the negative electrode should contain three times the weight of platinum in the positive electrode. With finely-divided palladium a storage capacity of 176 ampere-hours per kilogram of palladium was obtained at a pressure of 600 atmospheres. It is interesting to note that the storage capacity of an ordinary lead accumulator is about 15 ampere-hours per kilo of metal.

LEON GUIGNARD, in the *Journal de Botanique*, adds another important contribution to our knowledge of the centrospheres of plant-nuclei, entitled "Sur l'origine des sphères directrices." It will be remembered that this author was the first to demonstrate the existence of these structures in vegetable cells (*Comptes-rendus*, 1891), and also, in a later paper, to describe their behaviour during the origin of the sexual cells and the part they take in the phenomena of fertilisation (*Ann. des Sc. Nat.* 1891). In these earlier works Guignard already figured many resting nuclei with the centrospheres lying outside the nuclear membrane, and usually in close proximity to it, while within the nuclear membrane are to be seen one or more nucleoli. Strasburger also observed and figured centrospheres outside resting nuclei in *Sphacelaria scoparia* (*Hist. Beiträge*, iv. p. 52). Recently, however, G. Karsten was led to believe, from a study of the relations of the nucleoli and centrosomes in the mother cells of the spores of *Psilotum triquetrum* that the centrosomes (or minute bodies included in the centrospheres) owe their origin to the nucleoli, and after karyokinesis are re-included as nucleoli in the daughter nuclei. Guignard's last paper is chiefly concerned with an examination of this point, and he comes to the conclusion that prior to karyokinesis the centrospheres in the cells of the sporangia of *P. triquetrum* are external to the nuclear membrane, and that after karyokinesis, while some of the small nucleoli which have not disappeared during the division of the nucleus are re-included within the nuclear membranes of the daughter nuclei, they remain external to them.

A RECENT number of the *Minnesota Botanical Studies* contains a bibliography on the subject of the fixation of free nitrogen by plants, embracing over 600 titles.

THE report of the fifth meeting of the Australasian Association for the Advancement of Science, held at Adelaide, in September 1893, has just reached us from Sydney, where the permanent office of the Association is situated.

MESSRS. RIVINGTON, PERCIVAL, AND CO. have published a third edition of "Practical Inorganic Chemistry," by Mr E. J. Cox. The book is intended for students preparing for the elementary practical chemistry examination of the Department of Science and Art.

IN the form of "Bulletin No. 56," Mr. P. H. Mell, the State Botanist for Alabama, records the result of a series of observations on the crossing of different varieties of the cotton-plant at the Agricultural Experiment Station at Auburn. The plant is pollinated by the agency of the wind and of insects, and he finds inter-crossing to have a material effect in increasing the strength of the fibre.

MISS ORMEROD will issue in a few days an abstract of information on the history and habits of that seriously destructive cattle-pest, the Warble Fly or Ox Bot Fly. The description will be very fully illustrated, and will be an epitome of the knowledge and experience gained up to the present time, and especially during the years 1884 to 1894. It will deal practically with means of prevention and remedy. The publishers are Messrs. Simpkin, Marshall, Hamilton, Kent, and Co.

AN "Artificial Spectrum Top," devised by Mr. C. E. Benham, and sold by Messrs. Newton and Co., furnishes an interesting phenomenon to students of physiological optics. The top consists of a disc, one half of which is black, while the other half has twelve arcs of concentric circles drawn upon it. Each arc subtends an angle of forty-five degrees. In the first quadrant there are three such concentric arcs, in the next three more, and so on; the only difference being that the arcs are parts of circles of which the radii increase in arithmetical progression. Each quadrant thus contains a group of arcs differing in length from those of the other quadrants. The curious point is that when this disc is revolved, the impression of concentric circles of different colours is produced upon the retina. If the direction of rotation is reversed, the order of these tints is also reversed. The cause of these appearances does not appear to have been exactly worked out.

THE additions to the Zoological Society's Gardens during the past week include a Black Lemur (*Lemur macaco*, ♂) from Madagascar, presented by Mr. Roche; a Snowy Owl (*Nyctea scandiaca*), captured in mid-Atlantic, 700 miles from land, presented by Mr. Harston Eagle: two Levaillant's Cynictis (*Cynictis levaillanti*), two Domestic Sheep (*Ovis aries*, var.), two Puff Adders (*Vipera arietans*), a Cape Bucephalus (*Bucephalus capensis*), six Hispid Lizards (*Agama hispida*), five Rough-scaled Lizards (*Zonurus corydlus*), a Delalande's Lizard (*Nucras delalandi*), a Crossed Snake (*Psammophis crucifer*) from South Africa, two Bennett's Tree Kangaroos (*Dendrolagus bennethanus*) from North Queensland; an Allied Goshawk (*Astur approximans*), three Long-necked Chelodines (*Chelodina longicollis*), twenty-two Golden Tree Frogs (*Hyla aurea*), seventeen White's Tree Frogs (*Hyla cærula*) from Australia, a Spix's Macaw (*Ara spixi*) from North Brazil, deposited; two Caroline Conures (*Conurus carolinensis*) from North America, purchased; two Queensland Tree Kangaroos (*Dendrolagus lumholtzi*, ♂ ♀) from Queensland; four Brush Turkeys (*Talegalla lathami*, 4 ♂) from Australia, received in exchange.

OUR ASTRONOMICAL COLUMN.

THE PARALLAX OF NEBULA *h* 2241.—At the time when Dr. Wilsing took photographs of the nebula B.D. + 41°·4004 for the determination of parallax, he obtained also a series of negatives of B.D. + 41°·4773 (*h* 2241) for the same purpose. This nebula is almost ring-shaped, and displays a central condensation. The latter appears more distinct on the photographic plates than can be seen by eye observations, and its contour is only sufficiently sharp for micrometric measurements on the best plates, so that the centre of the whole apparent disc has been generally used. From June 1892 to August of the following year, 33 plates were obtained, 31 of which have been used in this research. Six comparison stars, the positions of which were taken from the Bonn zones, have been adopted. In the account of the result obtained (*Astro. Nach.* No. 3261), Dr. Wilsing gives a table showing the deduced distances of the nebula from the two comparison stars 3 and 6. A second table contains the mean monthly values of these distances with their differences from the whole *mean* value obtained from all the measurements, together with the most probable errors of the measurements.

The following table shows these differences between the total and monthly means for the two stars 3 and 6:

	[N, 3]	[N, 6]	Prob. error.	No. of plates.
	"	"	"	
1892 June 21	−0·03	+0·28	±0·08	5
July 13	+0·11	+0·03	0·06	9
Aug. 9	+0·07	−0·04	0·13	2
Sept. 25	+0·01	−0·06	0·08	5
Oct. 4	−0·13	+0·01	0·13	2
Nov. 8	+0·20	+0·03	0·10	3
Dec. 22	−0·53	−0·44	0·18	1
1893 Feb. 4	−0·13	−0·34	0·18	1
July	−0·08	−0·19	0·13	2
Aug.	−0·53	−0·14	0·18	1

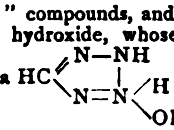
These differences, when considered in relation with the probable errors of the measurements, have as Dr. Wilsing suggests, to be cautiously dealt with, and he is led to conclude from this series of measures that the relative parallax of this nebula does not exceed one or two tenths of a second of arc.

A POSSIBLE NEW ZONE OF ASTEROIDS.—The secular variations of the orbits of the four inner planets has lately occupied Prof. Newcomb's attention, with the result that several elements have been found to vary in a manner unaccounted for by existing theory. (*Astronomical Journal*, No. 327.) "These anomalies," says Prof. Newcomb, "cannot be simultaneously explained either by an intra-mercurial zone of planets, by the action of matter reflecting the zodiacal light, or by a deviation of gravitation from the usually accepted law. The uncertainty as to the mass of Mercury makes the construction even of a working hypothesis difficult; but apart from all considerations of probabilities, *à priori*, the hypothesis which best represents observations, is that of a ring of planetoids of small eccentricity a little outside the orbit of Mercury, and a little more inclined to the ecliptic. The total mass of the ring may range from one-fiftieth to, perhaps, one three-hundredth of the mass of Venus, according to its distance from Mercury." Prof. Newcomb intends to carefully investigate the matter in order "to decide whether the results of the hypothesis are such as to counterbalance its extreme improbability."

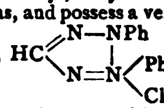
A NEW COMET.—*Edinburgh Circular*, No. 43, dated November 23, states that a telegram received from the Central Astronomical Station at Kiel announces the discovery of a very faint comet, by Mr. Edward Swift, at 8 p.m., Californian time, on the 20th inst. It was situated in Right Ascension, 22h. 18m. 24s., and South Declination, 13° 7′, and was moving slowly towards the east.

A NEW SERIES OF NITROGEN COMPOUNDS.

ANOTHER new series of nitrogen compounds, containing four atoms of that element along with one atom of carbon in a closed chain, are described by Prof. v. Pechmann and Herr Runge in the current *Berichte*. They are termed "tetrazolium" compounds, and the parent base of the series is tetrazolium hydroxide, whose constitution is represented by the formula



. The fundamental base itself has not yet been isolated; the compounds prepared comprise the derivative in which the two hydrogen atoms directly attached to the two end nitrogen atoms are replaced by phenyl, together with a large number of salts of this base, formed by replacement of the hydroxyl by halogens or other acid radicles just as in the case of metallic hydroxides. The hydrogen atom attached to the carbon is likewise capable of replacement by many organic radicles, so that a large number of still more complicated bases have likewise been prepared, together with their corresponding salts. The hydroxides of this new series are characterised by possessing strong basic properties. They may all be prepared most conveniently from their chlorides, by the action upon them of silver oxide. They are extremely soluble in water, but are completely precipitated from their solutions by ether. The aqueous solutions absorb carbon dioxide and behave very much like caustic alkalies. They cannot, however, be crystallised, forming resins upon concentration. The salts, on the other hand, crystallise admirably; they are usually soluble in water, react neutral to litmus, and possess a very bitter taste. Diphenyl tetrazolium chloride,



which may be taken as a typical salt of the series, crystallises in colourless radiating groups of needles very sensitive to light, which renders them yellow. The aqueous solution yields a flesh-coloured precipitate of a chloroplatinate with platinum chloride, and the double salt may be crystallised from hot water. A crystalline double chloride is likewise produced with gold chloride. The addition of a soluble nitrate or iodide causes the precipitation of the difficultly soluble nitrate or iodide of the base. A solution of iodine in potassium iodide precipitates an iodine addition product, which can be crystallised from alcohol in beautiful brown tabular crystals exhibiting a violet reflection. The parent base is produced in solution upon the addition of silver oxide, silver chloride being likewise formed. The chloride is reduced by ammonium sulphide to a compound of the constitution: $HC\begin{cases} N-NHPh \\ N=NPh \end{cases}$, a substance which Prof. v. Pechmann has previously described, and which is interesting as forming the starting-point for the preparation of the new series. For the chloride may at once be prepared from this latter substance by oxidation with amyl nitrite and hydrochloric acid. The substance is readily prepared by the action of diazobenzene chloride upon malonic acid, constituting the insoluble product of the reaction. It is of considerable interest to observe that the main product of the dry distillation of diphenyl tetrazolium chloride is azobenzene.

THE SCIENTIFIC INVESTIGATIONS OF THE SCOTTISH FISHERY BOARD.

THE Twelfth Annual Report of the Fishery Board for Scotland (Part III. Scientific Investigations for 1893) contains a quantity of new information upon fishery problems, and marks an important stage in the history of the Board, owing to the successful inauguration during the past year of a hatchery at Dunbar for the artificial propagation of marine food-fishes.

A number of important conclusions are formulated by the Board upon various matters. In the first place, the closure of the territorial waters to beam-trawling is admitted to have had no appreciable effect towards arresting the continued decline in the supply of flat-fishes, although the interdicted area has been very large. The greater part of the territorial waters of the East Coast, the Firth of Forth, and St. Andrews Bay have been protected (except for experimental purposes) since 1886, and this area was greatly extended in 1889, when practically the whole of the territorial waters and several extensive bays (the Firth of Clyde and the Moray Firth) were closed against the operations of the beam-trawler. The reason for the failure of this method of protection is sought for in the fact that the present protected area does not embrace the spawning grounds of food-fishes, except in the case of the Moray Firth. It is most unfortunate that, from lack of a sufficiently seaworthy vessel, the Board has been unable to devote the same attention to the Moray Firth as to the Firth of Forth and St. Andrews Bay, for statistics upon the condition of the Moray Firth throughout the year would have been invaluable. But it can be definitely asserted that the mere protection of areas that do not include spawning grounds is practically useless to prevent depletion of the home fisheries. The recommendation of the recent Parliamentary Committee that the present territorial limit should be considerably extended, is accordingly endorsed; and, in order to ensure the enclosure of the more important breeding-grounds, the Board emphasises its recommendation of the previous year, that the limit of jurisdiction should be extended to ten or twelve miles from shore.

Experiments have been made upon the effects of alteration in the size of the mesh of the beam-trawl upon the capture of immature fish. It was found that, contrary to the opinion of most practical men at the recent Parliamentary inquiry, the size of the mesh has a most appreciable influence in determining the size of the fish captured. Dr. Fulton's effective experimental trawlings show that the proportion of fishes that escape through the cod-end of the trawl increases greatly as the width of the meshes is enlarged.

Prof. M'Intosh gives an interesting review of the trawling question in general, and includes a valuable sketch of the changes which have taken place during the past ten years in trawling-vessels and their apparatus. Reasons are adduced which tend to show that line-fishing is quite as destructive as trawling to immature round fishes, such as cod and haddock; and it is maintained that the perennial abundance of the floating fauna, of which larval stages of bottom-animals form so large a proportion, is sufficient to prevent the trawling-grounds from being depleted of fish-food to any serious extent.

The volume includes a number of papers of a more purely biological character upon the development of fishes, on the invertebrate fauna of the Firth of Forth and certain inland lochs, on the oviposition and rate of growth of the sand-eel and certain other fishes, and on some seasonal changes in the histology of fishes. Two papers on the osteology of the tunny and on the anatomy of the pectoral arch in the gurnard seem to us to be completely out of place in an official publication ostensibly devoted to fishery investigations, with which they have nothing to do.

Turning to Prof. M'Intosh's "Remarks on Trawling," justifiable as his general position appears to be, he has, nevertheless, left himself open to criticism on a number of minor points. It is difficult to reconcile with the statistics of the *Garland* trawlings the Professor's remark that "the closure of the inshore waters—*e.g.* St. Andrews Bay—must have conduced to the prosperity of the turbot and the brill of that neighbourhood, most of the turbot (ranging from 9 to 11 inches) *which formerly were captured by the trawlers* now being unmolested" (p. 167). For in Dr. Fulton's introductory report on the work of the *Garland* it is stated that in St. Andrews Bay, as in the Firth of Forth, there was an actual decrease in 1893 of "turbot and brill" in the closed areas as compared with 1892 (p. 26); and the decrease of flat-fishes in general during the eight years of closure is demonstrated on p. 33. Moreover, out of the twenty-four experimental trawlings conducted by the *Garland* in the closed waters of St. Andrews Bay in 1893 only two turbot, and no brill at all, were obtained. Indeed, the average take of turbot was twice as great in the unprotected as in the protected areas of the Bay (p. 42).

In one of the most interesting sections of his "Remarks" (p. 184), Prof. M'Intosh discusses the "effect of trawling on the invertebrate fauna of the sea-bottom (forming fish-food)." It is full of valuable observations from the rich stores of the Professor's experience, but, as an argument, seems to us to be vitiated by a very questionable assumption which underlies it, viz. that all invertebrate life on the sea-bottom furnishes food for fishes. Half the groups, at least, which are mentioned by the Professor in this connection should, in our opinion, be eliminated, viz. sponges, hydroids, anemones, alcyonaria, star-fishes, balani, and ascidians, although we are quite prepared to allow that now and then, in exceptional cases, particular species of some of these groups may be swallowed by fishes. Therefore the Professor's argument that the trawl causes little impoverishment of the supply of fish-food, owing to the rapid powers of growth and repair which the above groups (among some others) possess, is seriously impaired.

In Mr. Harald Dannevig's Report (p. 211) we notice the interesting observation that fishes which spawn during the night in open ponds will do so during the day also if the pond be darkened.

Coming to the biological investigations, we observe that Prof. M'Intosh has overlooked (p. 227) the fact that the Norwegian Topknot (*Zeugopterus norvegicus*) has been recorded by Mr. Cunningham as occurring in considerable numbers at Plymouth (*Jour. M.B.A.* ii. 1892, p. 325). In connection with Mr. Sandeman's investigations on seasonal changes in the histology of fishes, attention may be drawn to another paper by Mr. Cunningham (*Jour. M.B.A.* ii. 1891, pp. 16-42), in which a number of remarkable histological changes are shown to take place in the female conger during the period of the maturation of her eggs.

The main results of Mr. Dickson's physical investigations in the Faröe-Shetland seas seem to us to be of profound importance. If, as he contends, a mass of Atlantic water is every year admitted through the Faröe-Shetland Channel, winds round the Shetlands, and bores its way down the eastern coasts of Scotland in the summer months, guided by a bank of dense water in the upper regions of the North Sea, it is clear that we have at once an explanation of numbers of isolated facts of occasional or periodic distribution of pelagic animals in those regions, which have hitherto seemed merely freaks of Neptune or Æolus. And it cannot be doubted that a further extension of such investigations as Mr. Dickson has been carrying out in H.M.S. *Jackal*, if coupled with a corresponding survey of the pelagic fauna, will provide the long-sought solution of the migrations of the herring and other nomad fishes round our coasts.

In congratulating the Board upon its scientific achievements for the year, we cannot help expressing our intense regret that the recently vacant chairmanship was not offered by the Government to Dr. John Murray. His experience and energy would at all times be invaluable, but at the present juncture, when so many important fishery problems of a physico-biological nature are pressing for solution, the loss to the Board and to the country of his counsel and aid is incalculable. W. G.

SIR JOHN DONNELLY ON TECHNICAL EDUCATION.

AT the first ordinary meeting of the new session of the Society of Arts, Major-General Sir John Donnelly delivered an address in which he dealt with some points in the history of the Society, and especially with those connected with the promotion of education. The following is a condensed report of his remarks bearing upon the development of technical instruction:—

In 1868, a Conference on Technical Education was held by the Society of Arts, and shortly afterwards—on March 24, 1868—on the motion of Mr., now Sir B. Samuelson, Bart., the House of Commons granted a Select Committee, of which he was appointed chairman, "to inquire into the provisions for giving instruction in theoretical and applied science to the industrial classes." The first three of their conclusions were—(1) That, with the view to enable the working classes to benefit by scientific instruction, it is of the utmost importance that efficient elementary instruction should be within the reach of every child; (2) that unless regular attendance of the children for a sufficient period can be obtained, little can be done in the way of their scientific instruction; (3) that elementary instruction in drawing, in physical geography, and in the phenomena of nature should be given in elementary schools. Throughout these discussions the object-lesson afforded by the Paris Exhibition of 1867 was universally acknowledged to be the main feature of the movement.

Sir John Donnelly brought before the Society in 1872 a scheme for examinations in technology, which were to be supplementary to the examinations of the Science and Art Department. The scheme did not meet with much enthusiasm, and manufacturers set themselves against it on the grounds that trade secrets should not be the talk of the class-room. However, since then the examinations have been very largely developed by the City and Guilds of London Institute.

Owing to a set of circumstances, with which everyone is now thoroughly conversant, there was, shortly after the passing of the Technical Instruction Act, in 1889, a great windfall for technical instruction. Under the Customs and Excise Act of 1890, the residue, amounting to something over three-quarters of a million of money in England and Wales, became applicable to technical education. It has been so applied very largely. From a recent return it appears that, of the forty-nine County Councils, excluding Wales and Monmouth, forty-one are applying the whole, and eight a part of the residue to technical education. Of the sixty-one County Boroughs, fifty-three are applying the whole, and seven a part of the residue to technical education; while in one case only (the County Borough of Preston) the residue is being applied wholly to relief of rates. Further than this, ten County Boroughs are, in addition, levying a rate under the Technical Instruction Acts.

For the year 1893–94, the forty-nine County Councils have allocated about £465,000, and the County Boroughs about £161,000 from the Customs and Excise grant, besides raising over £12,700 by rates. This makes a total of almost exactly £626,000 provided in England alone for technical instruction for the year, independent of the grants from the Science and Art Department.

It is purely at the option of local authorities whether they apply the "beer" money to technical education, or whether they use it in relief of the rates. It is very gratifying to see the extent to which they have devoted it to the former object, and it shows that the operations of the Science and Art Department, the Society of Arts, the City and Guilds of London, and other bodies which had previously been engaged in the movement, have not been unfruitful. But unquestionably a great danger lurks around a sudden outburst or zeal of this kind. How far have the public generally been convinced of the efficacy of science and art and technical instruction, and the advantage of spending all the money on it, rather than in relief of rates? or how far have they been only momentarily carried away unwilling captives at the chariot-wheels of the enthusiasts? How soon will the pendulum of public opinion which has been so suddenly and so severely forced in one direction swing back again? Or—a still greater danger—how soon will the critic, the cynic, and the "practical" man commence their innings by asking to have the account balanced and the profit shown? There are already murmurings in the air: did not our forefathers get on very well without technical education? or how is it that we stand—or, at least, stood—at the head of manufacturing and commercial fame and engineering ability? At all events, if you cannot show any fruit let us have an inquiry; dig up the plant and have a look at its roots to see that we have planted the right sort.

Now what is this "technical instruction" with which the country is so much occupied at the present time? It is defined in the Act of 1889 as instruction in the principles of science and art applicable to industries, and in the application of special branches of science and art to specific industries or employments, as well as in modern languages and commercial and agricultural subjects, but not in teaching the practice of any trade, or industry, or employment.

The Act, in fact, provides for instruction in technology and not in technics. Besides, though the definition clause is careful to indicate that the principles of science and art are to be cultivated, the title of the Act appeals to the sympathy of the great mass who always clamour for a short cut—some way for arriving at the money-making application of science and of art without that preliminary study which is so laborious and apparently unremunerative.

After dwelling upon changes of style in artistic work and design, Sir John Donnelly went on to say that every now and then we hear a great outcry against South Kensington and its "system." And if South Kensington now, why not in a few years hence the technical schools and courses of instruction which are being set up with so much care and thought in all parts of the country? This danger is already felt by many who are interested in technical instruction. The Science and Art Department could always point to the fact that, if its science teaching was wrong, it erred in good company, for the syllabuses were prepared, and the examinations were conducted by some of the most eminent men of science of the day.

But to whom can the local authorities under the Technical Instruction Act appeal? It seemed to him that for their own satisfaction, and for the future stability of technical instruction, they will desire, instead of remaining, as it were, isolated and self-contained, to have an influential examining and inspecting board, to which they might refer, if they found it desirable, for assistance and advice. There are at present several bodies partially covering the ground—but only partially, and there is the great disadvantage of a want of unity. He threw out the suggestion that the Society of Arts, which is at present covering part of the field, should take the initiative in bringing all these bodies together, so that they may form some kind of joint board, or at least co-operate.

THE BATTLE OF THE FORESTS.[1]

I.

THE earth is a potential forest. Given time, freedom from geologic revolutions and from interference by man, the tree growth must finally dominate everywhere, with few excepted localities.

Its perennial nature and its elevation in height above all other forms of vegetation, together with its remarkable recuperative powers, assure to the arborescent flora this final victory over its competitors.

So impressed was Dr. Asa Gray with the persistence of individual tree life that he questioned whether a tree need ever die: "For the tree (unlike the animal) is gradually developed by the successive addition of new parts. It annually renews not only its buds and leaves, but its wood and its roots; everything, indeed, that is concerned in its life and growth. Thus, like the fabled Æson, being restored from the decrepitude of age to the bloom of early youth, the most recent branchlets being placed by means of the latest layer of wood in favourable communication with the newly-formed roots, and these extending at a corresponding rate into fresh soil, why has not the tree all the conditions of existence in the thousandth that is possessed of in the hundredth or the tenth year of its age?

"The old and central part of the trunk may, indeed, decay, but this is of little moment, so long as new layers are regularly formed at the circumference. The tree survives, and it is difficult to show that it is liable to death from old age in any proper sense of the term."

[1] A lecture delivered by Prof. B. E. Fernow, Chief of the Forestry Department of Agriculture, U.S.A., during the Brooklyn meeting of the American Association for the Advancement of Science.

However this may be, we know trees succumb to external causes. Nevertheless, they are perennial enough to outlive aught else, "to be the oldest inhabitants of the globe, to be more ancient than any human monument, and exhibit in some of the survivors a living antiquity compared with which the mouldering relics of the earliest Egyptian civilisation, the pyramids themselves, are but structures of yesterday." The dragon trees, so called, found on the island of Teneriffe, off the African coast, are believed to be many thousand years old. The largest is only 15 feet in diameter and 75 feet high. Our sequoias are more rapid growers, and attain in 3000 to 4000 years, which may be the highest age of living ones, more than double these dimensions.

While this persistence of life is one of the attributes which in the battle for life must count of immeasurable advantage, the other characteristic of arboreal development, its elevation in height above everything living, is no less an advantage over all competitors for light, the source of all life. Can there be any doubt that in this competition size must ultimately triumph, and the undersized go to the wall?

Endowed with these weapons of defensive and offensive warfare, forest growth, through all geologic ages during which the earth supported life, has endeavoured, and no doubt to a degree succeeded, in gaining possession of the earth's surface.

As *terra firma* increased emerging in islands above the ocean, so increased the area of forest, changing in composition to correspond with the change of physical and climatic conditions.

As early as the Devonian age, when but a small part of our continent was formed, the mud flats and sand reefs, ever increasing by new accumulations under the action of the waves and currents of the ocean, were changed from a bare and lifeless world above tide level to one of forest-clad hills and dales.

Not only were such quaint forms as the tree rushes Calamites, Lepidodendron and Sigillaria present, but the prototype of our pine, the Dadoxylon, had made its appearance.

The same class of flowerless plants known as vascular cryptogams, with the colossal tree ferns added, became more numerous and luxuriant in the Carboniferous age, as well as the flowering Sigillaria and coniferous Dadoxylon. This vegetation probably spread over all the dry land, but the thick deposits of vegetable remains accumulating in the marshy places under dense jungle growth and in shallow lakes with floating islands, were finally, in the course of geologic revolutions, turned into the great coal fields.

In those and subsequent geologic times some of the floral types vanished altogether and new ones originated, so that at the end of Mesozoic times a considerable change in the landscape had taken place.

In addition to coniferous trees, the palms appeared, and also the first of angiosperms, such as the oak, dogwood, beech, poplar, willow, sassafras, and tulip tree. Species increased in numbers, adapted to all sorts of conditions; the forest in a most varied and luxuriant form climbed the mountain-sides to the very crests, and covered the land to the very poles with a flora of tropical and semi-tropical species.

Then came the levelling process and other changes of post-Tertiary or Quaternary times; the glaciation of lands in northern latitudes, with the consequent changes of climate, which brought about corresponding changes in the ranks of the forest, killing out many of the species around the north pole. Only the hardier races survived, and these were driven southward in a veritable rout.

When these boreal times subsided in a degree, the advance of the forest was as sure as before, but the battle order was somewhat changed to suit the new conditions of soil and climate. Only the hardiest tribes could regain the northernmost posts, and these found their former places of occupancy changed by fluvial and lacustrine formations and the drifts borne and deposited by the ice-sheets, while some by their constitution were entirely unfitted from engaging in a northern campaign, or found insurmountable barriers in the refrigerated east-west elevations of Europe and Western Asia.

In addition, there had come new troubles from volcanic eruptions, which continually wrested the reconquered ground from the persistent advance guards of the arboreal army, annihilating them again and again.

Finally, when the more settled geologic and climatic conditions of the present era arrived, and the sun rose over a world ready for human habitation, man found what we are pleased to call the virgin forest—a product of long-continued evolutionary changes—occupying most, if not all the dry land, and ever intent upon extending its realm.

This prehistoric view of the battle of the forest cannot be left without giving some historic evidences of its truth.

Not only have palæobotanists unearthed the remnants of the circumpolar flora, which give evidence that it resembled that of present tropic and semi-tropic composition, but they have also shown that sequoias, magnolias, liquidambars and hickories existed in Europe and on our own continent in regions where they are now extinct. We have also evidences of the repeated successes and reverses of the forest in its attempts to establish itself through long geologic transformations.

One of the most interesting evidences of these vicissitudes in the battle of the forest is represented in a section of Amethyst Mountain in Yellowstone National Park, exhibiting the remains of fifteen forest growths, one above the other, buried in the lava. Again and again the forest subdued the inhospitable excoriations; again and again it had to yield to superior force.

Among these petrified witnesses of former forest glory, magnolia, oak, tulip tree, sassasfras, linden and ash have been identified, accompanying the sequoia in regions where now only the hardiest conifer growths of pines and spruces find a congenial climate.

As the forest formed and spread thus during the course of ages, so does it form and spread to-day, unless man, driven by the increasing needs of existence, checks its progress and reduces its area by the cultivation of the soil. This natural extension of the forest cover or afforestation takes place readily whenever soil and climate is favourable, but it is accomplished just as surely, though infinitely slower, in unfavourable situations. On the naked rock, the coarse detritus and gravel beds, on the purely siliceous sand deposits of river and ocean, or in the hot dry plains, the preliminary pioneer work of the lower vegetation is required. Algæ, lichens, mosses, grasses, herbs, and shrubs must precede to cultivate the naked rock, to mellow the rough moisture by shading the ground, and gradually render it fit for the abode of the forest monarch. The army of soil-makers and soil-breakers, the pioneers, as it were, of the forest, are a hardy race, making less demands for their support than those that follow. They come from different tribes, according to the soil conditions in which they have to battle.

The aspen (*Populus tremuloides*) is one of these forerunners, which is readily wafted by the winds over hundreds of miles, readily germinates and rapidly grows under exposure to full sunlight, and even now in the Rocky Mountains and elsewhere quickly takes possession of the areas which man has ruthlessly destroyed by fire. This humble and ubiquitous, but otherwise almost useless, tree is nature's restorative, covering the sores and scalds of the burnt mountain side, the balm poured upon grievous wounds. Though short-lived, with its light summer foliage turning into brilliant golden autumn hues, it gives grateful shade and preserves from the thirsty sun and wind some moisture, so that the better kinds may thrive and take its place when it has fulfilled its mission.

One of the shrubs or half-trees which first take possession of the soil in the western mountain country is the so-called mountain mahogany (*Cercocarpus ledifolius*), covering the bared slopes after the fire has killed the old timber.

In other regions, as on the prairies of Iowa and Illinois, hazel bushes, or in the mountains of Pennsylvania and the Alleghanies in general, ericaceous shrubs like the laurel and rhododendrons or hawthorn, viburnum and wild cherry are the first comers, while along water-courses alders and willows crowd even the water into narrower channels, catching the soil which is washed from the hill-sides and increasing the land area.

One of the most interesting soil-makers, wresting new territory from the ocean itself, is the mangrove along the coast of Florida. Not only does it reach out with its aerial roots, entangling in their meshes whatever litter may float about, and thus gradually building up the shore, but it pitches even its young brood into the advance of the battle, to wrestle with the waves, and gain a foothold as best it may.

Not less interesting in this respect is that denizen of the southern swamp, the bald cypress, with its curious root excrescences known as cypress knees, which, whatever their physiologic significance, are most helpful in expediting changes of water into land sufficiently dry to be capable of supporting the more fastidious species in regard to moisture and conditions.

On the dry hot mesas, and in the arroyos of the south-western tier of our States and Territories, we meet a different set of skirmishers following up the huge cacti and agaves, which together with the tree yuccas, penetrate into the very desert. In these regions the mesquite or algaroba and others of the acacia tribe form the second phalanx, as it were, gradually advancing their lines in spite of adverse conditions. In other regions the pine, satisfied with but scanty favour of soil moisture, and the spruce, able to sustain life in shallow soil, and the fir, in the higher, colder, and wetter elevations, sometimes much stunted, form the skirmish line. These improve the soil in its moisture conditions by their shade, and by the foliage and litter falling and decaying they deepen the soil, forming a humus cover. The duff that is found covering the rocky subsoil of the Adirondacks is formed in this way at the rate of about one foot in 500 years. They are soon followed by the birch, maple, elm, and ash, and in moister situations by the oak—first, that hardy pioneer, the black oak tribe, and then the more fastidious white oak, with whom the slower but persistent hickories, beeches, and other shade-enduring species begin to quarrel for the right of occupancy of the ground, until the battle is no longer that of the forest against the elements and lower vegetation, but between the mighty conquerors themselves. This struggle we can see going on in our primeval forests, wind, storms, and decay acting as allies now to one, now to the other side, and thus changing the balance of power again and again.

In this struggle for supremacy between the different arborescent species the competition is less for the soil than for the light, especially for tree growth. It is under the influence of light that foliage develops, and that leaves exercise their functions and feed the tree by assimilating the carbon of the air and transpiring the water from the soil. The more foliage and the more light a tree has at its disposal, the more vigorously it will grow and spread itself.

Now the spreading oak or beech of the open field finds close neighbours in the forest, and is narrowed in from all sides and forced to lengthen its shaft, to elevate its crown, to reach up for light, if it would escape being overshadowed, repressed, and perhaps finally killed by more powerful densely-foliaged competitors.

The various species are differently endowed as regards the amount of light which they need for their existence. Go into the dense forest and see what kinds of trees are vegetating in the dense shade of the older trees, and then go into the opening recently made, an abandoned field or other place, where the full benefit of light is to be had by all alike, and one will find a different set altogether occupying the ground and dominating. In the first case there may be found, perhaps, beech and sugar maple or fir and spruce; in the second case aspen, poplar, willow, soft maple, oak or pine, tamarack, &c.

All trees thrive ultimately best in full enjoyment of light. But some, like those first mentioned, can at least subsist and their foliage functionate with a small amount—they are shade-enduring kinds, usually having a dense foliage, many leaves, and each one needs to do but little work—and exert considerable shade when fully developed. Those last named, however, are light-needing kinds, and having less foliage, cannot exist long without a considerable amount of light.

To offset this drawback in the constitution of these latter, nature has endowed them as a rule with the capacity of rapid height growth, to escape their would-be suppressors; but again, what they have gained in the rapidity of development they lose in the length of life. They are mostly short-lived species, while the shade-enduring are generally slower growers, but persistent and long-lived. Some kinds, like most of the oaks, stand between the two; while exhibiting a remarkable capacity of vegetation in the shade, they are really light-needing species, but comparatively slow-growers and long-lived. One of the same species behaves also somewhat differently under different soil and climatic conditions; for instance, as a rule, the light-needing species can endure more shade on moist soils, and the shade-enduring require more light on drier soils.

In the earliest stages of life the little seedlings of most trees require partial shade, and are quite sensitive in regard to light and conditions. Some have such a small range of light and shade endurance that, while there may be millions of little seedlings sprouted, they will all perish if some of the mother trees are not removed and more light given; and they will perish equally if the old growth is removed too suddenly, and the delicate leaf structure, under the influence of direct sunlight, is made to exercise its functions beyond its capacity.

Left to itself the forest grows up, and as the individual trees develop, each trying to hold its ground and struggling for light, a natural thinning takes place, some trees lagging behind in growth and being shaded out, until in old age only as many trees remain as can occupy the ground without incommoding each other.

This struggle among the individuals goes on during their entire life. Some few shoot ahead, perhaps, because of a stronger constitution or some favourable external cause, and over-tower their neighbours. These, lagging behind, fall more and more under the shading influence of their stronger neighbours until entirely suppressed, when they only vegetate until they die. The struggle continues, however, among the dominant class, and it never ends.

Thus the alterations of forest growth take place, oak following pine, or pine following oak; the poplar, birch and cherry appearing on the sunny burns, or the hickory, beech, and maple creeping into the shadier pine growths. While in the eastern forests under natural conditions the rotation of power is accomplished in at least from 300 to 500 years, the old monarchs of the Pacific, towering above all competitors, have held sway 2000 or more years. In this warfare, with changes in climatic and soil conditions going on at the same time, it may well occur that a whole race may even be exterminated.

The study of the formative period of the forest is necessary in order to show clearly that the virgin forest is a product of long struggles, extending over centuries, nay, thousands of years. Some of the mightiest representatives of the old families, which at one time of prehistoric date were powerful, still survive, but are gradually succumbing to their fate in our era.

The largest of our eastern forest trees, reaching a height of 140 feet and diameters up to twelve feet, the most beautiful and one of the most useful, the tulip tree (*Liriodendron tulipifera*), is a survivor of an early era, once widely distributed, but now confined to eastern North America, and doomed to vanish soon from our woods through man's improper partisanship.

Others, like the Torreya and Cupressus, seem to have succumbed to a natural decadence, if we may judge from their confined limits of distribution. So, too, the colossal sequoias, remnants of an age when things generally were of larger size than now, appear to be near the end of their reign, while the mighty taxodium or bald cypress, the big tree of the East, still seems vigorous and prosperous, being able to live with wet feet without harm to its constitution, weird with the grey tillandsia or Spanish moss.

Having thus scanned through the traditions of unwritten history of the battle of the forest, having seen some of the combatants in the struggle, and learned something of their methods of conquering the earth and each other, we may take a look at the condition of things on the North American continent as it presumably was in the beginning of historic times or within our century.

As far as occupancy of the soil by the forest is concerned, we find that the struggle had not yet been determined in its favour everywhere. While a vast territory on the Atlantic side and a narrower belt on the Pacific Coast, connected by a broad belt through the northern latitudes, was almost entirely under its undisputed sway, and while the backbone of the continent, the crest and slopes of the Rocky Mountains, was more or less in its possession, there still remained a vast empire in the interior unconquered.

Of parts of this territory we feel reasonably certain from strong evidences that the forest once occupied them, but has been driven off by aboriginal man, the firebrand taking sides with the grasses, and the buffalo probably being a potent element in preventing re-establishment. In other parts it is questionable whether the lines along the river-courses, the straggling trees on the plateaus and slopes, are remnants of a vanquished army or outposts of an advancing one. In some parts, like the dry mesas, plateaus and arroyos of the interior basin and the desert-like valleys toward the southern frontiers, it may reasonably be doubted whether arborescent flora has more than begun its slow advance from the outskirts of the established territory.

Certain it is that climatic conditions in these forestless regions are most unfavourable to tree growth, and it may well be questioned whether in some parts the odds are not entirely against the progress of the forest.

Temperature and moisture conditions of air and soil determine ultimately the character of vegetation, and these are dependent not only on latitude, but largely on configuration of the land, and especially on the direction of moisture-bearing winds with reference to the trend of mountains.

The winds from the Pacific Ocean striking against the coast range are forced by the expansion and consequent cooling to give up much of their moisture on the windward side; a second impact and further condensation of the moisture takes place on the Cascade range and Sierra Nevada. On descending, with consequent compression, the wind becomes warmer and drier, so that the interior basin, without additional sources of moisture and no additional cause for condensation, is left without much rainfall and with a very low relative humidity, namely, below 50 per cent. The Rocky Mountains finally squeeze out whatever moisture remains in the air currents, which arrive proportionally drier on the eastern slope. This dry condition extends over the plains until the moist currents from the Gulf of Mexico modify it. Somewhat corresponding, yet not quite, to this distribution of moisture, the western slopes are found to be better wooded than the eastern, and the greater difficulty of establishing a forest cover here must be admitted; yet since the forest has the capacity of creating its own conditions of existence by increasing the most important factor of its life, the relative humidity, the extension of the same may only be a question of time.

Temperature extremes, to be sure, also set a limit to tree growth, and hence the so-called timber line of high mountains, which changes in altitude according to the latitude.

If now we turn our attention from the phyto-topographic consideration of the forest cover to the phyto-geographic and botanical features, we may claim that the North American forest, with 425 or more arborescent species, belonging to 158 genera, many of which are truly endemic, surpasses in variety of useful species and magnificent development any other forest of the temperature zone, Japan hardly excepted. In addition there are probably nowhere to be seen such extensive fields of distribution of single species.

These two facts are probably explained by the north-and-south direction of the mountain ranges, which permitted a re-establishment after the Ice Age of many species farther northward, while in Europe and the main part of Asia the east-west direction of the mountains offered an effectual barrier to such re-establishment, and reduced the number of species and their field of distribution; nor are the climatic differences of different latitudes in North America as great as in Europe, which again predicates greater extents in the fields of distribution north and south. On the other hand, the differences east and west in floral composition of the American forest are greater than if an ocean had separated the two parts instead of the prairie and plains. This fact would militate against our theory that the intermediate forestless region was or would be eventually forested with species from both the established forest regions, if we did not find some species represented in both regions and a junction of the two floras in the very region of the forestless areas.

(*To be continued.*)

SOCIETIES AND ACADEMIES.

LONDON.

Zoological Society, November 20.—Sir W. H. Flower, K.C.B., F.R.S., President, in the chair.—Mr. F. G. Parsons read a paper on the anatomy of *Atherura africana*, compared with that of other porcupines. In addition to the points mentioned by Drs. Gray and Günther, as differences between the skulls of *A. africana* and *A. macrura*, the arrangement of the fronto-nasal suture, the position of the maxillo-malar suture, and the frequent presence of an "*os anti-epilepticum*" were noticed.—A communication from Mr. J. T. Cunningham treated of the significance of diagnostic characters in the Pleuronectidæ.—Mr. A. Smith Woodward read a description of the so-called Salmonoid fishes of the English Chalk, dealing with the osteology of *Osmeroides lewesiensis*, *Elopopsis crassus*, and *Aulolepis typus*.—Mr. W. Garstang read a paper on the Gastropod *Colpodaspis pusilla* of Michael Sars. He described a specimen of this rare mollusk found by him at Plymouth in the early part of the year.—A communication from Mr. A. D. Bartlett gave an account of the recent occurrence in the Society's menagerie of a case of one boa swallowing another of nearly equal size.—A communication from Prof. R. Collett contained a description of a new Agonoid fish from Kamtschatka, proposed to be called *Agonus gilberti*.

Royal Meteorological Society, November 21.—Mr. R. Inwards, President, in the chair.—Dr. H. B. Guppy read a paper on suggestions as to the methods of determining the influence of springs on the temperature of a river as illustrated by the Thames and its tributaries. The methods suggested were (1) comparison of the curves of the monthly means of the temperatures of the air and of the water for the river under observation with those of a river beyond the controlling influence of springs; (2) comparison of the monthly means of the temperature of the river under investigation with that of a river beyond the control of the springs; (3) comparison of the range of the monthly means of the river temperature with that of the air in the shade; (4) comparison of the daily range of water temperature at different stations along a river's course; (5) comparison of sunrise observations made at different stations along a river's course; (6) comparison of observations made at different stations along a river's course at the hour of maximum temperature; (7) comparison of the results obtained from a single series of observations made in one day along the whole course of a small tributary like the Wandle, or along the upper course of a larger tributary as the Kennet; and (8) determination of the distance from its sources at which the river begins to freeze.—Mr. Eric S. Bruce exhibited and described some lantern slides showing the disastrous effects of the great gale of November 17 and 18, 1893, upon trees in Perthshire, Scotland.—Mr. Alfred B. Wollaston gave an account of the formation of some water-spouts which he had observed in the Bay of Bengal.

CAMBRIDGE.

Philosophical Society, November 12.—Prof. J. J. Thomson, President, in the chair.—On the inadequacy of the cell theory and on the development of nerves, by Mr. A. Sedgwick. The author pointed out that the cell-theory, in so far as it implied that the organism was composed of cell-units derived by division from a single primitive cell-unit, the ovicell, would not bear the scrutiny of modern embryology, and that in fixing men's attention too much upon the cell as a unit of structure, it had had a retarding influence on the progress of the knowledge of structure. He illustrated this latter point by reference to the current ideas on two important subjects: the structure of the embryonic tissue called mesenchyme, and the development of nerves. The mesenchyme is not composed of separate branched cells, but has rather a spongy or reticulate structure, and is continuous both with ectoderm and endoderm. Nerves do not develop as outgrowths of the central organ, but arise *in situ* from the mesenchyme.—Note on the evolution of gas by water-plants, by Mr. F. Darwin.

PARIS.

Academy of Sciences, November 19.—M. Lœwy in the chair.—After the reading of the *procès verbal*, the meeting was adjourned as a mark of respect to the late Czar of Russia.

AMSTERDAM.

Royal Academy of Sciences, October 27.—Prof. Van de Sande Bakhuyzen in the chair.—Mr. Franchimont, in presenting Mr. H. van Erp's thesis for the Doctorate in Chemistry at the University of Leyden, entitled "Studie ober aliphatische nitraminen," described it as a summary of all the known acid and neutral nitramines and nitramides, and also of their modes of formation. In dealing with the action of water, acids and alkalies on these bodies, Mr. van Erp considers them as derived from the amide of nitric acid, and compares them to the analogous derivatives of nitrous acid, hypochlorous acid, &c. For experimental purposes he made the unknown butyl- and hexyl-derivatives: nine urethanes, seven nitro-urethanes, four acid nitramines with several salts, two mixed neutral nitramines. He failed, however, to obtain nitro-compounds of the tertiary butyl amidoformates. He has observed that while the potassium salts of the acid nitramines yield the neutral methyl-derivatives by the action of methyliodide, the silver salts produce an isomeric methylated nitramine, or a mixture of the two. Similar observations in the case of the salts of phenylnitramine were made later by Bamberger. The behaviour of acid nitramines towards dilute sulphuric acid was studied on hexylnitramine, the result being N_2O, two hexanoles, a primary and a secondary

(2 ?), hexene (1) and a dihexylic ether. Mr. van Erp has also observed the behaviour of neutral nitramines with alkalies. Dimethylnitramine gives nitrous acid, monomethylamine, formic acid (and methyl alcohol ?). Diethyl- and dipropylnitramine seemed not to be changed. Normal butylmethylnitramine, less easily than dimethylnitramine, gives nitrous acid, butylamine, formic acid (and methyl alcohol ?). It therefore seems that mixed nitramines give the amine with the greatest alkyl, or the methyl radical is most easily separated from the nitrogen.—On quadrinodal quintics, by Mr. Jan de Vries.—On the cranial nerves of vertebrates in amphioxus, by Mr. van Wijhe. The olfactory nerve represents a type of its own. The ventral nerves, or nerves of the myotomes, do not exhibit special characteristics. Among the dorsal or septal nerves, the trigeminal, facial, glossopharyngeal and vagus nerves could be recognised with more or less probability, chiefly by their relations to the branchial clefts, the first of which on the left side becomes the opening of the velum.

DIARY OF SOCIETIES.

LONDON.

THURSDAY, NOVEMBER 29.

SANITARY INSTITUTE, at 8.—Workers in Copper, Zinc, Brass, and Tin: Dr. R. M. Simon.

FRIDAY, NOVEMBER 30.

ROYAL SOCIETY, at 4.—Anniversary Meeting.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Sub-aqueous Excavation at Newry: C. H. Olley.

SANITARY INSTITUTE, at 8.—Sanitary Law: Prof. A. Wynter Blyth.

SUNDAY, DECEMBER 2.

SUNDAY LECTURE SOCIETY, at 4.—Village Life in India: Mr. R.W. Frazer.

MONDAY, DECEMBER 3.

SOCIETY OF ARTS, at 8.—Modern Developments in Explosives: Prof. Vivian B. Lewes.

SOCIETY OF CHEMICAL INDUSTRY (Burlington House), at 8.—The Rational Sterilisation of Alimentary Liquids: Mr. E. W. Kuhn (of Paris).—An Investigation of the Natural Sodium Sulphate Lakes of Wyoming, U.S.A.: Dr. D. H. Attfield.—Specimens of India-rubber, and Petroleum Oil, Varnish, and Soap will be exhibited by Mr. Thos. Christy.

VICTORIA INSTITUTE, at 4.30.—Semitic Languages: Mr. T. G. Pinches.

TUESDAY, DECEMBER 4.

ZOOLOGICAL SOCIETY, at 8.30.—On some Points in the Anatomy of Ornithorhynchus paradoxus: Mr. T. Manners Smith.—On certain Points in the Visceral Anatomy of Ornithorhynchus: Mr. F. E. Beddard, F.R.S.—On some Remarkable Corals of Great Size from North-West Australia: Prof. F. Jeffrey Bell.—Second Report on Additions to the Lizard Collection in the Natural History Museum: Mr. G. A. Boulenger, F.R.S.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Machinery of War-Ships: Mr. Albert J. Durston.—Colliery Surface-Works: Mr. E. B. Wain.

ROYAL STATISTICAL SOCIETY, at 4.45.—The Eleventh United States Census: Hon. R. P. Porter.—Exhibition of the Hollerith Electrical Counting Machine: Dr. H. Hollerith.

WEDNESDAY, DECEMBER 5.

SOCIETY OF ARTS at 8.—Fire Protection: Edwin O. Sachs.

GEOLOGICAL SOCIETY, at 8.—Supplementary Note on the Narborough District (Leicestershire): Prof. T. G. Bonney, F.R.S.—The Tarns of Lakeland: Mr. J. E. Marr, F.R.S.—The Marble Beds of Natal: Mr. David Draper.—Description of a New Instrument for Surveying by the Aid of Photography, with some Observations upon the Applicability of the Instrument to Geological Purposes: Mr. J. Bridges Lee.

ENTOMOLOGICAL SOCIETY, at 8.—A List of the Lepidoptera of the Khasia Hills, Part III.: Colonel Charles Swinhoe.—A Monograph of British Braconidæ, Part VI.: Rev. T. A. Marshall.—On the Longicorn Coleoptera of the West India Islands: Mr. Charles J. Gahan.—Notes on the Fungus Growing and Eating Habit of Sericomyrmex opacus, Mayr.: Mr. F. W. Urich.—An Apparent Case of Sexual Preference in a Male Insect: Prof. E. B. Poulton, F.R.S.

THURSDAY, DECEMBER 6.

ROYAL SOCIETY, at 4.30.—Experimental Researches on Vegetable Assimilation and Respiration. No 1. On a New Method for Investigating the Carbonic Acid Exchanges of Plants. No. 2: On the Paths of Gaseous Exchange between Aerial Leaves and the Atmosphere: Mr. F. F. Blackman.

SOCIETY OF ARTS, at 4.30.—Roman and British Indian Systems of Government: Hon. W. Lee-Warner, C.S.I.

LINNEAN SOCIETY, at 8.—A New Revision of Dipterocarpeæ, with Lantern Slides: Sir D. Brandis, F.R.S.—On the Spinning Glands in Phrynus: Mr. H. M. Bernard.

CHEMICAL SOCIETY, at 8.—The Use of the Globe in the Study of Crystallography: J. Y. Buchanan, F.R.S.—Latent Heat of Fusion: Mr. H. Crompton.—New Method of Preparing Dihydroxytartaric Acid: Mr. H. J. H. Fenton.—Essential Oil of Hops: Mr. A. C. Chapman.

LONDON INSTITUTION, at 6.—The Fauna of Rivers and Lakes: Prof. Sydney Hickson.

FRIDAY, DECEMBER 7.

ROYAL INSTITUTION, at 5.—General Monthly Meeting.

GEOLOGISTS' ASSOCIATION, at 8.—Note on Megalosaurian Teeth, discovered by Mr. J. Alstone in the Portlandian of Aylesbury: Mr. A. Smith Woodward.—On the Geology of the St. Gothard Pass: Mr. H. W. Monckton.

SATURDAY, DECEMBER 8.

ROYAL BOTANIC SOCIETY, at 3.45.

BOOKS, PAMPHLETS, and SERIALS RECEIVED

BOOKS.—Imperial University of Japan, Calendar 1893-4 (Tōkyō Maruya).—Catalogue of the Snakes in the British Museum (Natural History): G. A. Boulenger, Vol. 2 (London).—The Flower of the Ocean, the Island of Madeira: Surgeon-General C. A. Gordon (Baillière).—Topographische Anatomie des Pferdes: Ellenburger and Baum, Zweiter Teil (Berlin, Parey).—Butterflies and Moths (British): W. Furneaux (Longmans).

PAMPHLETS.—Sulle Oscillazioni Elettriche a Piccola Lunghezza d'Onda &c.: Prof. A. Righi (Bologna).—North of England Institute of Mining and Mechanical Engineers: Report of the Proceedings of the Flameless Explosives Committee. Part 1. Air and Combustible Gases: A. C. Kayll (Reid).—Resultate der im Sommer 1893 in dem Nördlichsten Theile Norwegens ausgeführten Pendelbeobachtungen: O. E. Schiötz (Kristiania, Dybwad).

SERIALS.—Cassell's Magazine, December (Cassell).—Proceedings of the Aristotelian Society, Vol. 2, No. 3, Part 2 (Williams).—Transactions and Proceedings of the Botanical Society of Edinburgh, Vol. xx. Part 1 (Edinburgh).—Proceedings of the American Academy of Arts and Sciences, new series, Vol. xxi. (Boston).—Brain, Part lxviii. (Macmillan).—Kryptogamen-Flora von Schlesien, iii. PECULIARITIES OF PSYCHICAL RESEARCH.

Apparitions and Thought Transference. By Frank Podmore, M.A. (London: Walter Scott, 1894.)

MR. PODMORE, in the opening chapter of this popular exposition of telepathy, pleads for the recognition of psychical research by the general body of scientific workers. He reminds us of the opposition geological and biological discoveries have encountered, and ventures to compare the circumstances of the small group of investigators with which he is connected, and more particularly the prejudice and derision they encounter, with the experiences of Cuvier and Agassiz. Convincing as this comparison may appear to the general reader, in one respect at least it fails. Three hundred years ago, all these phenomena of crystal gazing, thought transference, and apparitions had a broader basis of belief than they have to-day; even a hundred years ago, the ordinary scientific investigator was at little or no advantage over the exponent of magic arts. But though, as Mr. Podmore reminds us, the leading propositions of natural science once encountered popular prejudice, ridicule, contempt, hatred, far more abundantly than has ever been the lot of psychical interpretations, they have won through and triumphed, while the credit accorded such evidence as the S.P.R. accumulates has, if anything, diminished. A thing Mr. Podmore scarcely lays sufficient stress upon is the fundamental difference in the quality of the facts of "psychical research," as distinguished from those of scientific investigation—using scientific in its stricter sense. It is true he has, with an appearance of frankness, devoted a chapter to "special grounds of caution," in which he concedes the truth of various criticisms, and owns to several undeniable impostures; but even here he passes from admissions to a skilful argument in favour of telepathy, and avoids the cardinal reason for keeping aloof from this field of inquiry, that lies in the quality of the evidence.

The scientific advances of Cuvier and Agassiz, like all true scientific discoveries, were based upon things that could be perceived directly by themselves, and which could be reproduced whenever required, and completely examined under this condition and that, by those who doubted the facts. That is the essential difference between natural science and such a subject as history; science produces its facts, history at best produces reputable witnesses to facts. Scientific men have never attached much importance to unverifiable statements, however eminent the source. If, to suppose an instance, the greatest living anatomist were to announce that he had dissected a dogfish and discovered lungs therein, adduce his wife, a local general practitioner, two servants, and a lady "named Miss Z." in evidence, and add that he had lost the specimen, there can be scarcely any doubt that, in spite of his position and his character, the science of anatomy would remain exactly where it was before his discovery was proclaimed. But in this "psychical research" the deliberate reproduction of phenomena under conditions that admit of exhaustive sceptical examination appears to be generally impossible, and we are repeatedly asked to form opinions on the hearsay of Mr. Podmore and his fellow-investigators.

This is not all. Few of the phenomena are directly observed. Dr. Dee had his Kelly, Prof. Oliver J. Lodge his Mrs. Piper. If Prof. Sedgwick would read the thoughts of Prof. Oliver J. Lodge, or—as a phantasm of the living—take to haunting some sceptical person, we should have at least a statement at first hand, to doubt; but as it is, these investigators manifest, as a rule, no other mental phenomena than belief and repetition. Reading through Mr. Podmore's book, the student will be struck by the fact that the persons who are in immediate contact with the alleged phenomena, the hireling eyes of the psychological inquirer, are persons usually youthful and coming from a social level below that of the investigators. Take, for instance, the Guthrie cases, to which Mr. Podmore attaches considerable importance. Mr. Guthrie is a draper in Liverpool, and by some means, not stated, he became aware of psychic powers possessed by two of his employees—young ladies—whose identity is for some reason veiled under the initials "E." and "R." These young ladies were accordingly liberated at intervals from the toils of shop or workroom, and made the subjects of various experiments; Mr. Guthrie, for instance, putting cayenne pepper in his mouth, during a profound silence, and Miss E. experiencing a taste of "mustard." Now we must insist upon the fact, because it seriously affects this question of evidence, that to a young lady following the irksome and precarious calling of a draper's assistant, the manifestation of psychic gifts opens up eminently desirable possibilities and interests. Then, among other of these intermediaries, we find "Jane"—a pitman's wife —"Bertha J.," a peasant woman, hospital nurses and out-patients, two men "who had been subjects of an itinerant lecturer upon hypnotism," most of the letters of the alphabet, several American M.D.'s, lady medical students, a baker's assistant, Mr. P., "a clerk in a wholesale house, aged nineteen, who possesses a good deal of humour," and so forth.

Scarcely ever is the medium a person really independent, in a financial sense, of the investigators who are craving for phenomena. It is necessary for us to believe in the general good faith of this extremely dubious material, or in the adequacy of the precautions against fraud taken by persons whose scientific reputations are now hopelessly bound up with the reality of the alleged facts, before one can even begin to accept the experimental basis upon which the theory of telepathy rests. And this is the character of the investigations that Mr. Podmore has compared with the work of Cuvier and Agassiz! In no other field of inquiry is so much faith in personal character and intelligence demanded, or so little experimental verification possible. Indeed, the book is oddly suggestive in places, with its use of initials and second-hand guarantees of character, of the testimony one finds adduced in favour of patent medicines.

Now, to the attentive reader of Mr. Podmore, the persuasion is unavoidable that the ordinary psychical investigator is endowed with a considerable facility of belief, and is by no means instinct with the scientific method. And this, where we are to take very much on faith, is a material consideration. Anonymous statements are accepted, and not only anonymous but self-contradictory ones. Mrs. Piper hypnotised, personated a French physician Dr. Phinuit, who did not know French, and failed to give a satisfactory account of himself. Mrs. Piper, during her trance as Dr. Phinuit, gabbled, made chance shots, "fished" for information, and was generally a transparent enough imposition. Yet she occasionally spoke of things she could not, according to the investigators, have obtained a knowledge of by ordinary means. For that they give her credit, and forgive all her failures. Prof. Lodge, apparently eager to believe, compares her utterances to the experience of anyone listening at a telephone: "you hear the dim and meaningless fragments of a city's gossip till back again comes the voice obviously addressed to you, and speaking with firmness and decision." Imagine in a real scientific inquiry an investigator pursuing a theory through a complicated series of observations, arbitrarily selecting those that advance his views, and calling the others "dim and meaningless until back comes the result obviously addressed to you!"

As one instance of the absence of scientific method from these discussions, take M. Richet's and Mr. Gurney's experiments with cards. In these experiments an agent looked at the card, and a percipient guessed the suit. M. Richet conducted 2927 trials, and 789 correct guesses were made, the theory of probability only granting 732. The S.P.R. trials numbered 17,653, with 4760 successes—347 in excess of the probable number. Now this is adduced by Mr. Podmore as evidence for telepathy; we are asked to believe that about once in sixty times—that is the excess above the probable ratio of successes—the mental impression of the agent recorded itself upon the brain of the percipient. Whether during the interval of fifty-nine trials telepathy was in abeyance, Mr. Podmore does not say, and the failure of the American S.P.R. to confirm these results he sets aside because the details of their experiments are not given—an excellent example to the sceptic. Are we to believe that only once in sixty times did the transferred thought surge up into consciousness, or that the transference occurs only at the sixtieth time, or what? A most obvious collateral test seems to have been altogether overlooked, namely, for someone to guess cards *before* the agent saw them, and so to ascertain how far pure haphazard guessing of this kind, or guessing on any particular gambler's "system," may fall away from the theory of probability. The deductions of the theory of probability, be it remembered, become certainties only when the number of cases is infinite. We have no grounds for assuming that in seventeen thousand or seventy thousand, or in any finite number of cases, facts come into coincidence with this theory. In an infinite number of sets of 17,653 trials we might have every possible divergence from the average result up to 17,653 successive failures or 17,653 successive successes. Taking a number of sets, they may be expected to fluctuate round a mean result in agreement with the theory of probability—that is all. These three sets of experiments manifestly prove nothing. And this is how Mr. Podmore prefaces his account of them: "In the following cases, where the exact nature of the impression received was not apparently classified by the percipient, it may be presumed to have been either of a visual or an auditory nature." He begs the question, and in a book addressed to the untrained mind of the general reader! Nothing could show more clearly the tendency of this psychical research to accept as evidence what is really not evidence at all, its lack of critical capacity and severe confirmatory inquiry, and the missionary spirit of its exposition.

Enough has been said to show the essential difference between "psychical" and scientific investigations, and to justify the attitude of scepticism. After all, that scepticism does nothing to hamper Mr. Podmore and his associates from collecting their evidence, clarifying their opinions, and building up such a defensible case as their peculiar circumstances permit. And be it remembered the scientific man of to-day occupies a responsible position, that he possesses even a disproportionate share of the public confidence, because of his reputation for sceptical caution. The public mind is incapable of the suspended judgment; it will not stop at telepathy. Any general recognition of the evidence of "psychical" research will be taken by the outside public to mean the recognition of ghosts, witchcraft, miracles, and the pretensions of many a shabby-genteel Cagliostro, now pining in a desert of incredulity, as undeniable facts. Were Mr. Podmore's case strong—and it is singularly weak—the undeniable possibility of a recrudescence of superstition remains as a consideration against the unqualified recognition of his evidence.

H. G. WELLS.

THE BEGINNINGS OF HISTORY.

The Dawn of Civilisation—Egypt and Chaldæa. By G. Maspero. Edited by A. H. Sayce. Translated by M. L. McClure. (London: Society for Promoting Christian Knowledge, 1894.)

AS the winter season advances, and folk begin to wend their way to Egypt, the enterprise of authors and publishers keeps up a steady supply of good literature concerning the country which, since the English occupation in 1882, has exercised upon people of all nations a fascination which may be described as marvellous. Only a few weeks ago an English translation of Dr. Erman's *Aegypten* appeared, and already we have before us a translation of a very important work by Prof. Maspero in the same language. Both works are excellent, but each is typical of the nationality of its writer, and is really addressed to a different class of readers. The work of Dr. Erman possesses a minuteness of detail characteristic of the true German student, laborious and accurate, while that of M. Maspero, though no less accurate, discusses facts on a large scale with due reference to everything which bears upon them, and contains generalisations which all thoughtful readers will accept with gratitude; added to this, we have the light and easy style and logical arrangement of facts and sentences which are the type of the work of the French master of his subject. In short, Dr. Erman's book will form a standard work of reference for the student of Egypt; but that of M. Maspero will take its place as a general history of early Oriental civilisation on the banks of the Nile, Tigris, and Euphrates, and in the countries which lie between.

The volume which we have in our hands, although it is nowhere stated in it, seems to be the first of a series which M. Maspero intends to devote to the history of the ancient nations of the East; and indeed the original French work began to appear in weekly numbers with the general title of *Histoire Ancienne des Peuples de l'Orient* some time ago. It is necessary to state this in order that the reader may not confuse the new work of M. Maspero with the small and older work, the first edition of which appeared in Paris so far back as 1875, for although both books run on the same lines, and have the same aim, and the smaller originated the idea of the larger, yet the scale of the new work has been so greatly increased that it practically forms a new and independent treatise on Oriental history and archæology. The first work ran through four editions at least, and was exceedingly popular; but the new work, with its beautiful illustrations, is intended to be in France what Rawlinson's "Ancient Monarchies" was in England.

M. Maspero divides the first volume of his history into two parts: the first treats of Egypt, and the second of Ancient Chaldæa, six chapters being devoted to the former subject, and three to the latter. A detailed description of the formation of Egypt as a land is followed by an account of the Nile and of its influence upon the history of the country and its people. The civilisation of Egypt, according to M. Maspero, sprang up in the country on the banks of the Nile, which was bounded by Gebel Silsila on the south, Butó in the Delta on the north, the mountain of Bakha on the east, and the mountain of Manu on the west. The origin of the people who produced it is difficult to trace, for the camp of Egyptologists is divided in opinion on the matter. Many scholars hold that the Egyptians came from Asia, but not all who are of this opinion agree as to the route followed by them into Egypt. Some would have them enter Egypt by the Isthmus of Suez, and having gained possession of the Delta, make their way up to Memphis, Heliopolis, and further south; others would have them cross the Red Sea to Kosseir and so thence to Coptos, and thus account partially for the traditions which made Abydos in Upper Egypt the oldest city in Egypt; and again, others would make them cross over from the Arabian Peninsula by the Straits of Bâb el-Mandeb into Africa, and skirting the Abyssinian mountains, enter Egypt from the south. The first theory holds water so long as we assume that the Egyptians made their way from the East by the old trade routes into Egypt through Syria; in fact, this would be their only way if they set out from countries on about the same parallel of latitude as Babylon, for the want of water in the desert between the Euphrates and Egypt has from time immemorial made the route impossible even for the armies of mighty kings, and every invasion of Egypt by peoples from this region has been made by the way of northern Syria. The second theory makes it necessary for the emigrants from Asia to have crossed the waterless desert in the Arabian Peninsula, and to have built boats sufficiently large to cross the Red Sea; this appears to be the most improbable of all the theories yet put forth. The third theory has much in its favour, for the passage across the Straits of Bâb el-Mandeb would be easy, and the distance from shore to shore was probably less in those days than now. There exists yet another theory, however, as to the Asiatic origin of the Egyptians. In a paper read at the Oriental Congress in 1892, Dr. Hommel boldly asserted that the Egyptian civilisation was derived from that of Babylon, and he attempted to prove that the names of the gods of the one country were but slightly modified forms of those of the others. Egyptologists have not, up to the present, accepted this theory. A still more remarkable theory is that of Reinisch, who believes that Asiatics, Europeans and Africans spring from one family, whose original home was in the heart of Africa, near the great equatorial lakes. M. Maspero does not accept the theory of an Asiatic origin, but rather believes that the Egyptian

"population presents the characteristics of those white races which have been found established from all antiquity on the Mediterranean slope of the Libyan continent; this population is of African origin, and came to Egypt from the west or south-west. In the valley, perhaps, it may have met with a black race which it drove back or destroyed; and there, perhaps, too, it afterwards received an accretion of Asiatic elements, introduced by way of the isthmus and marshes of the Delta."

The caution with which M. Maspero puts forth this theory shows that he has some doubts about it, and, indeed, leaves the question exactly where it was. As to the relationship between the Semitic languages and the language of the hieroglyphics, he has no doubt that at one time they all belonged to the same group; the latter, however, separated from the former very early, "at a time when the vocabulary and the grammatical system of the group had not as yet taken definite shape." This is an important pronouncement for an Egyptologist to make, and although it was said long ago by Semitic scholars, it is none the less welcome since it comes from one of the first Egyptologists of our times. Passing from the origin of the people to their religion and manners and customs, M. Maspero concisely and graphically describes their gods and mythology, and the beliefs which swayed the minds of the Egyptians for several thousands of years. The size of M. Maspero's work and the limits of a brief article absolutely preclude the possibility of noticing many new points in these subjects, which are admirably described, and we rapidly pass from the account of the political constitution of Egypt to the historical section of this division of the book, which treats of the first fourteen dynasties.

The second part of the volume follows the plan of the first, and sets out by describing the country, people, gods, &c., of the ancient Chaldæans, or more properly Babylonians, and the chapter which treats of their ideas concerning the Creation is of considerable interest. In this M. Maspero has rightly relied upon Jensen's epoch-marking book, "Die Kosmologie der Babylonier," for information, but it is to be regretted that Zimmern's translations of the "Creation" and other tablets were not published in time to be used by him. M. Maspero is, however, the first to describe popularly the excellent results achieved by Jensen in a subject which before he treated it was truly chaos. Passing to historical times, M. Maspero describes the foundation of the Babylonian empire, basing all his statements upon a series of works by Assyriological authorities, and cleverly harmonising their various opinions. The chapter on the Chaldæan civilisation is interesting, and is full of curious information. The volume is concluded by an appendix treating of the Pharaohs of the Ancient and Middle Empires, and by a useful index. M. Maspero is fortunate in having found so careful a translator as Mrs. McClure, who introduces her work in a preface which is at once business-like and to the point. The editor's remarks are, however, somewhat rambling, and in professing to criticise M. Maspero's knowledge of matters Egyptian or Babylonian, we think greatly out of place.

THE TRANSMISSION OF POWER.

On the Development and Transmission of Power. By William Cawthorne Unwin, F.R.S. (London: Longmans, Green, and Co., 1894.)

IT is well known that the author of this work has had special opportunities for studying the subject of transmission of power by all the various methods which have, at different times, been adopted, and the engineering world is to be congratulated on having received from his pen a summary of the principles utilised in this class of work, and of the possibilities of the future, as well as very complete and authentic information about the principal work that has been done in the past. This book is the outcome of a course of "Howard" lectures delivered before the Society of Arts in 1893. It deals with the generation, storage, and transmission or distribution of power. The methods of transmission and distribution include water under pressure, compressed air, wire ropes, steam, gas and electricity. The author recognises the fact that transmission of power to distances has not been so fully developed in the past as it is likely to be shortly, and that the electrical transmission and distribution of power has more to claim in the way of promises for the future than large achievements in the past.

The first chapters deal with the generation and the cost of generating power by steam or hydraulically. One of the most valuable parts of the book is found in those chapters where the economy of steam engines is considered. These chapters deal with the losses in boiler and engine in a very complete manner. The author has realised very fully the fact that in any case of generating power in large quantities, and distributing it to small consumers, the cost of the horse power depends largely upon the load curves at different times of the day, and he draws attention to the very large excess of cost per horse power of electric lighting stations over those which are delivering power at a constant rate. Even in a pumping station where the work is continuous, he finds that about 35 per cent. more fuel is required than in a careful trial, but in a station from which electric light or power is distributed, the losses due to banking of boilers and to engines working a portion of their time at an output which is not economical, are such that the quantity of fuel used per indicated horse power rises from 1½ lbs. per hour in a test trial with a condensing engine, to 3·3 lbs. under the special circumstances. The relative advantages of the condensing and non-condensing engines of the simple, compound, and triple expansion engines, of the steam-jacketing and superheating, are all discussed admirably. Some pages also are devoted to the utilisation of house refuse as a fuel, and the Halpin system of thermal storage receives some attention.

Some of the most important cases of utilising water power are also discussed. It will surprise many readers to find that even in 1876, 70,000-horse power was generated for manufacturing purposes from waterfalls in Switzerland, and that in the United States in 1880, 36 per cent. of the power used in manufacturing was water power, and only 64 per cent. steam power.

Among the chapters devoted to transmission of power, the most important, as pertaining more especially to the author's experience, are those on hydraulic and compressed air transmission. But in all branches of the subject, not only are the general principles dealt with, but there is to a pretty full extent a recapitulation of what has already been done. The London Hydraulic Power Company is taken as the best example of hydraulic transmission, but Liverpool, Birmingham and Manchester are also referred to, whilst most interesting accounts of the hydraulic supply at Zurich and Geneva are given. The principles of pneumatic distribution are very completely described, and the author has certainly made out the case that when these principles are properly applied, this system of distribution deserves more consideration than is generally accorded to it. Naturally the Paris distribution by this method is dealt with very fully, but other examples of interest are added. With regard to the distribution of power by steam, the most important case is that of New York, which Dr. Emery started in 1881. Eight pages upon gas distribution for power purposes are well worth some study, whether with regard to manufactured gas, or the natural gas supply in Pennsylvania. Whilst compressed air receives the author's attention to the extent of forty-eight pages, electrical distribution is by no means so well favoured; but the author explains that, in the first place, it is not his own speciality, and, in the second place, there are at the present moment few cases of electrical transmission combined with a complete system of distribution in a town. A chapter is at the end devoted to the great work which is now approaching its full development at Niagara Falls.

This short review cannot pretend to give an adequate idea of the contents or value of Prof. Unwin's book. Regarding the merits of the work generally, it is sufficient to say, first, that throughout it is written with the utmost fairness and impartiality; and secondly, that if any engineer were planning a system of transmission and distribution of power in any special case, he would be labouring under very considerable disadvantages if he had not first consulted this latest and most complete work on the development and transmission of power. G. F.

OUR BOOK SHELF.

A Treatise on Hygiene and Public Health. By Thomas Stevenson, M.D., F.R.C.P., and Shirley F. Murphy. (London: J. and A. Churchill, 1894.)

THIS volume is devoted to the subject of sanitary law, and it well maintains the all-round excellence of the two volumes that preceded it. Health-officers will welcome the appearance of such a lucid and comprehensive digest of the law relating to the public health in England and Wales, Ireland and Scotland.

During comparatively recent years an immense amount of piece-meal legislation bearing upon the public health has been passed; that much of this legislation, despite subsequent amendments, still remains obscure and unsatisfactory is clearly shown in the results of proceedings undertaken by those whose duty it is to put it in force. What cause to wonder, then, if the lay reader, by reason of obscurities in the particular Act itself, or from the fact that either amendments have been introduced by succeeding enactments or the particular Act is itself an amendment of earlier statutes, becomes bewildered, and a laudable desire to master an important subject is nipped in the bud? Those who are concerned in the administration of this branch of the law have frequent occasions to regret the lamentable ignorance existing among all sections of the community as to their powers and liabilities in matters which may seriously affect their vital interests. Any simplification and consolidation, therefore, more especially when it is undertaken, as in this instance, by gentlemen of recognised legal ability, should prove very welcome not only to health officers, but also to the general public.

The decisions of the authors of the work to collate the various provisions contained in different enactments dealing with the same subject, and to present these—so far as possible—freed of all legal phraseology, was a happy one; it makes the work unique in its serviceability to the lay reader, who will gain from its perusal a clearer and more definite knowledge of the public health laws of the different parts of the United Kingdom than he would succeed in doing—at a much greater sacrifice of time and patience—from any other publication dealing with the same subject.

Involution and Evolution according to the Philosophy of Cycles. By Kalpa. (London: Eyre and Spottiswoode, 1894.)

THIS is one of the books that most people would be glad to lay aside, and, indeed, it is very difficult to say with what object it has been written. The cycles decribed have nothing to do with approximate commensurability of planetary motions, and certainly not with evolution as understood in the modern acceptation of the term. The author is a disciple of the school of Mdme. Blavatsky, and draws his inspiration from that source, tinged, it may be, with something of esoteric Buddhism, and a good deal "spider-wove from his own brain." If anyone wants to know what absurdities modern theosophy is capable of, by all means let him read it, but most people will be satisfied to take the contents at second-hand. A very objectionable feature in the book is the occasional quotation at the heads of chapters of extracts from recognised writers of authority, conveying the impression that the contents of the chapters following are based upon modern science, and would meet the approval of the authors from whom the quotations are made. One illustration will be sufficient to show the style of the author's reasoning and the character of the information conveyed. The particular object is to demonstrate the birth of comets and worlds (p. 148). "But the least subtilised type of those disembodied groups does not take the same direction as the others. It keeps going in orbits round the sun, shooting beams at him, which, expelled (seemingly, at least), spread out behind as a lengthy tail. Then, when the sun takes a short rest, his brilliancy nearly spent, that entity moves off, its beams showing the way, but greatly reduced, and of which nought remains ere the *comet* disappears for parts unknown. It will be known to us as comet I." We have, approximately, 200 pages of this sort of stuff, paragraph after paragraph, all of which are utterly incomprehensible, and to wind up the whole we have sheet after sheet of diagrams or illustrations which no man can understand, and on which we should imagine the author himself would pass a very doubtful examination.

The Mountains of California. By John Muir. Pp. 381. (London: T. Fisher Unwin, 1894.)

FEW regions offer more remarkable subjects for the student of nature than the State of California. There are the two great mountain ranges—the Coast Range on the west, and the Sierra Nevada on the east. Great cañons furrow the latter to depths of from two thousand to five thousand feet, and in the middle of the deepest of them flourish the Sequoia, the noble sugar and yellow pines, Douglas spruce, Libocedrus, and the silver firs, each a giant of its kind. Floods of lava cover the north half of the High Sierra, and volcanic craters, recent and in all stages of decay, are dotted over it. Mount Shasta is one of these volcanic cones, rising to a height of more than fourteen thousand feet above sea-level. Deep grooves flute the sides of the mountains, and testify to glacial erosion. It appears that so far south as latitude thirty-six degrees, traces of glacial action abound. Mr. Muir has found sixty-five residual glaciers in the portion of the Sierra lying between latitudes thirty-six and thirty-nine degrees. The first one of these was discovered by him in 1871 between two of the peaks of the Merced group. He also determined the rate of motion of the middle of the Maclure glacier, near Mount Lyell, to be but little more than an inch a day. Mount Shasta has three glaciers; while Mount Whitney, though the highest mountain in the range, has none.

The special features of the volume are the descriptions of the glaciers, glacier lakes, and glacier meadows in the Californian mountains, and the interesting account of the grand forest-trees of the Sierra.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Origin of Classes among the "Parasol" Ants.

MR. J. H. HART is Superintendent of the Royal Botanic Gardens in Trinidad. He has sent me a copy of his report presented to the Legislative Council in March 1893, and has drawn my attention to certain facts contained in it concerning the "Parasol" ants—the leaf-cutting ants which feed on the fungi developed in masses of the cut leaves carried to their nests. Both Mr. Bates and Mr. Belt described these ants; but described, it seems, different, though nearly allied, species, the habits of which are partially unlike. As they are garden-pests, Mr. Hart was led to examine into the development and social arrangements of these ants; establishing, to that end, artificial nests, after the manner adopted by Sir John Lubbock. Several of the facts set down have an important bearing on a question now under discussion. The following extracts, in which they are named, I abridge by omitting passages not relevant to the issue:—

"The history of my nests is as follows: Numbers one and two were both taken (August 9) on the same day, while destroying nests in the Gardens, and were portions of separate nests but of the same species. No. 3 was procured on September 5, and is evidently a different although an allied species to Nos. 1 and 2.

"Finding neither of my nests had a queen, I procured one from another nest about to be destroyed, and placed it with No. 1 nest. It was received by the workers, and at once attended by a numerous retinue in royal style. On August 30 I removed the queen from No. 1 and placed it with No. 2, when it was again received in a most loyal manner. . . .

"Ants taken from Nos. 1 and 2 and placed with No. 3 were immediately destroyed by the latter, and even the soldiers of No. 3, as well as workers or nurses, were destroyed when placed with Nos. 1 and 2.

"In nest No. 2, from which I removed the queen on August 30, there are now in the pupa stage several queens and several males. The forms of ant in nests Nos. 1 and 2 are as follows: (*a*) queen (*b*) male (both winged, but the queen loses its wings after marital flight), (*c*) large workers, (*d*) small workers, and (*e*) nurses. In nest No. 3 I have not yet seen the queen or male, but it possesses—(*a*) soldier, (*b*) larger workers, (*c*) smaller workers, and (*d*) nurses; but these are different in form to those of nests No. 1 and No. 2. Probably we might add a third form of worker, as there are several sizes in the nest. . . .

"It is curious that in No. 1 nest, from which the queen was removed on August 30, new queens and males are now being developed, while in No. 2 nest, where the queen is at present, nothing but workers have been brought out, and if a queen larva or pupa is placed there it is at once destroyed, while worker larvæ or pupæ are amicably received. In No. 3 all the eggs, larvæ, and pupæ collected with the nest have been hatched, and no eggs have since made their appearance to date. There is no queen with this nest. . . . On November 14 I attempted to prove by experiment how small a number of 'parasol' ants it required to form a new colony. I placed two dozen of ants (one dozen workers and one dozen nurses) in two separate nests, No. 4 and No. 5. With No. 4 I placed a few larvæ with a few rose petals for them to manipulate. With No. 5 I gave a small piece of nest covered with mycelium. On the 16th these nests were destroyed by small foraging ants, known as the 'sugar' or 'meat' ant, and I had to remove them and replace with a new colony. My notes on these are not sufficiently lengthy to be of much importance. But I noted four eggs laid on the 16th, or two days after being placed in their new quarters; no queen being present. The experiment is being continued. I may mention that in No. 4 nest, in which no fungus was present, the larvæ of all sizes appeared to change into the pupæ stage at once for want of food [a fact corresponding with the fact I have named as observed by myself sixty years ago in the case of wasp larvæ]. The circumstance tends to show that the development of the insect is influenced entirely by the feeding it gets in the larvæ stage.

"In nest No. 2 before the introduction of a queen there were no eggs or larvæ. The first worker was hatched on October 27, or fifty-seven days afterwards, and a continual succession has since been maintained, but as yet (November 19) no males or queens have made their appearance."

In a letter accompanying the report, Mr. Hart says:—

"Since these were published, my notes go to prove that ants can practically manufacture at will; male, female, soldier, worker, or nurse. Some of the workers are capable of laying eggs, and from these can be produced all the various forms as well as from a queen's egg.

"There does not, however, appear to be any difference in the character of the food; as I cannot find that the larger larvæ are fed with anything different to that given to the smaller."

These results were obtained before the recent discussion of the question commenced, and as they agree with the results reached by Grassi in the case of the *Termites*, it can now scarcely be doubted that the various forms or classes among the social insects are wholly determined by the treatment of the larvæ.

St. Leonards, December 2. HERBERT SPENCER.

"Acquired Characters."

I DO not think we are in any way bound by the terms of the law enunciated by Lamarck. Those laws may be shown to be erroneous in all but the suggestion of a principle which may possibly be developed into an important and far-reaching doctrine, and if so the importance of the doctrine will be in nowise diminished by the crudity of the early suggestion. There is scarcely any scientific generalisation which does not require an amended enunciation in each generation if it is to be in accordance with the contemporary state of knowledge. Nevertheless it seems to me that the second law of Lamarck does not state that a character acquired by individuals *for the first time* is inherited, or "alters the potential character of the species." The law states that nature preserves by generation what has been acquired by individuals by the influence of the circumstances to which *their race* has been long exposed: *not* by the influence of the circumstances to which they alone have been exposed in their own individual existences.

Leaving Lamarck's laws and doctrines entirely out of the question, if we define an acquired character as one which is determined by the "operation on the individual of given and related quantities of external agencies," I am not aware that anyone has ever asserted that such a character is inherited, in the sense of being completely reproduced in the offspring without the operation of those external agencies. But I think there is reason to believe that if the same quantity of external agency acts on successive generations, it will produce more effect on the second than on the first, or, to use more correct language, that the effect in the second generation will be increased by a potentiality derived from the first. It is argued that the very possibility of the acquisition of new characters by the individual under new conditions is a proof that the old character had not become fixed and congenital after the action of the old condition on thousands of successive generations. But this is an illustration of the difficulty of completely expressing the problem in abstract language without reference to particular cases. If we consider the case of the pigmentation of the skin of the flounder, we find experimentally that exposure to light of the lower side for some years produces some pigmentation, but not so much as that on the upper side exposed in the individual for the same time. The action on the two sides in the individual being thus equal, or even greater on the lower side, how are we to account for the difference in favour of the upper? Evidently the congenital potentiality of the two sides is different. The old character has then become fixed and congenital to a certain very important degree. If no effect were produced by the action of light on the lower side of the individual, there would be no evidence that the congenital difference in the two sides had been produced by the difference in the relation to light repeated in countless successive generations. On the other hand, if the equal exposure of both sides produced equal pigmentation in the same time, this would be evidence that the difference in the pigmentation under normal conditions was not a congenital character at all. But as the facts stand, the only conclusion which is in accordance with them is that the congenital difference between the two sides is due to the gradual accumulation of slight effects on the congenital potentiality of the germ consequent upon the action of light in the individual. I could mention many other similar instances, which I think do constitute a reason for "associating the somewhat superficial and late responses of the parts of a growing individual to normal or abnormal forces of its environment with that more subtle and profound disturbance which is permanent and affects the potential character of the germ."

I am far, however, from supposing that all specific, generic, or morphological characters are due to the direct action of the environment in the soma, and equally far from admitting that every one of these characters has a part to play in the struggle for existence. J. T. CUNNINGHAM.

Plymouth, November 30.

THE distinction between the "acquired characters" of Lamarck and the other "responsive characters" which follow the "influence of the normal environment" is, I venture to think, not very important. The two kinds of characters are indeed admitted by Prof. Lankester to be "of the same order," and their essential unity is clearly shown when we attempt to trace the history of evolution as Lamarck conceived it.

The *first* increase in length of the neck of the giraffe or swan was no doubt, according to Lamarck, "an acquisition under *new* conditions of *new* character." But when the process had started, its subsequent stages could hardly be spoken of in this way. The effort of stretching, which was supposed to supply the condition for further increase, was then neither "new" nor "special and abnormal."

In the numerous discussions of the last seven years the term "acquired" has been employed to cover both classes of characters, and, indeed, the argument has chiefly turned on the effect of normal rather than abnormal and special conditions, because the evidence supplied by the former for or against hereditary transmission was so much more convincing than that supplied by the latter.

Although the term "acquired" is an unfortunate one, and has added many difficulties and obscurities which would have been avoided by the substitution of Prof. Lankester's term, "responsive," I think it would only increase the difficulties if it were now authoritatively maintained that, although the majority of instances discussed and the really crucial cases adduced are "of the same order" as acquired characters, they must no longer be called by this name.

I entirely agree with Prof. Lankester as to the mutual antagonism between the two laws of Lamarck. The first law assumes that a past history of indefinite duration is powerless to create a bias by which the present can be controlled; while the second assumes that the brief history of the present can readily raise a bias to control the future. EDWARD B. POULTON.

Oxford, December 2.

The Homing of Limpets.

IN NATURE, vol. xxxi. p. 200, Prof. Ainsworth Davis describes some observations he had made on the habits of the limpet. Marked individuals were found to return from their excursions, extending to a distance of some three feet, and to settle down on the spot which is their permanent home. By excision of the tentacles in two individuals Prof. Davis was led to conclude that it is not by these organs that the limpet finds its way back to its own particular scar. "The sense of smell then suggested itself, and it occurred to me," writes Prof. Davis, "that one reason why limpets kept on their scars when covered by the water was to prevent the scent being washed off. With a view to determine this, the space between a wandering limpet and its scar and the scar was carefully washed again and again with sea-water. In spite of this, the limpet in question readily found its way back again."

Last summer I had some opportunities of making observations at Mewps Bay, near Lulworth, in Dorsetshire. I trust that Prof. Davis will not consider a brief record of the results of these observations a case of unsportsmanlike poaching on his preserves.

The method I adopted was to remove the limpets from the rock and affix them at various distances from their scars. This can be done without difficulty or injury if one catches them as they are moving. But one must make sure that they are just leaving or returning to their own proper homes, and are not taken in the midst of a more extended peregrination, as in that case their special scars cannot be noted. Failure to be careful in this matter vitiated my earlier observations, which are therefore excluded in the following table:—

No. removed.	Distance in inches.	No. returned.		
		In 2 tides.	In 4 tides.	Later.
25	6	21	—	—
21	12	13	5	—
21	18	10	6	2
36	24	1	1	3

From the nature of the strata the removal to a distance of 12 inches or more generally involved taking the limpets over a corner of rock.

In most cases the individuals which failed to return to their respective scars took up new positions. In several cases when they were removed to a distance of a few inches from this new position they returned to it. In one case where the limpet had taken up such a new position it returned thereto after having been removed to its original scar.

Observation of the limpets without such experimental removal shows that they make their excursions in search of food chiefly as the tide leaves them and when it is returning. They generally seem to get back to the scar before the tide has well covered it. I have watched them return over considerable distances. In one case ten inches, over a somewhat curved course, was covered in a little under twenty minutes. In another case the limpet on its return journey had to pass between two other limpets, which necessitated the lifting of the shell to some height so as to pass over one of these. On reaching their scar they twist and turn about so as to fit down. When they come wrong way round they rotate pretty rapidly through the 180° to get into position. The final position on the scar is a constant one. One was observed to make a short excursion from and to return to its scar under stillish water. As a rule they seem to remain fixed under water.

The greatest distance I have watched a limpet reach from its scar was 22 inches. But I have found limpets at a distance of 3 feet from their scars—that is to say, from scars on to which they fitted perfectly. This was on a large flat surface.

When they move, the tentacles are projected out beyond the shell, and keep on touching and slightly adhering to the rock. On reaching the scar they carefully feel round it with the tentacles. I am disposed to question the results of Prof. Davis's experiments on the removal of the tentacles. But further observations and experiments are needed to settle the point. I understand that Prof. Davis is now at work upon the subject.

An injury to the edge of the shell seems to be repaired with whitish shell-material in the course of about ten days. And when a new position is taken up to which the shape of the shell is not suited, there appears to be a tendency for the shell to accommodate itself to the uneven surface of new growth along the edges. But this again is a matter on which further observation and experiment are required.

C. LLOYD MORGAN.

Gravitation.

THE nature of my suggestion (*vide* NATURE November 15, p. 57) is simply this:—A phenomenon of adhesion between solids immersed in a tensile liquid presents itself. The explanation offered (as I understand it) suggests that whether the bodies are attracted at long or short distances, will be a question entirely of the extension in the stressed medium of the modified layer. If this explanation be a correct one, or if any explanation involving a reaction between a modified layer (whether condensed or rarefied) and a *tensile* liquid will account for the phenomenon, then I say the experiment is a suggestive one as regards gravitation.

How far the modified layer will extend depends upon the law according to which the stress is distributed in the medium. In the case of matter acting upon matter at molecular distances we have reason to believe that the decrement of the stress is a rapid one. We possess no such knowledge when matter and ether alone are involved, and until we know how a modification of the ether around matter would display itself to our observation, I do not think the possibility of a remotely extended modification can be denied. Gravitation might be the sole resultant phenomenon affecting our senses. J. JOLY.

Trinity College, Dublin.

The Ratio of the Specific Heats of Gases.

I REMEMBER that in the discussion of eighteen years ago it was understood that you could get 1·4 for the ratio, if the molecules had each five degrees of freedom only—if they were, for instance, perfectly smooth, elastic spheroids. Probably the ultimate source of our knowledge in this respect was Boltzmann's paper, to which Mr. Bryan refers us. The difficulty at the time seemed to be mainly one of faith. One could not believe that the molecules were solid elastic bodies, however useful the discussion of such bodies might be in defining a limiting case. As the white posts along a road are put to show you where you should not go, not where you should go. It was further supposed, perhaps without sufficient reason, that the phenomena of the spectroscope required us to attribute many degrees of freedom to the molecules.

I hope Mr. Bryan will, as I have no doubt he can, develop his theory that all these phenomena can be accounted for by the electromagnetic theory of light, without attributing to the molecules more than five degrees of freedom. We have to explain, as it seems to me, how the ether will assume different sets of vibrations according to the shape of the bodies in contact with it. S. H. BURBURY.

1 New Square, Lincoln's Inn.

An Observation on Moths.

I THINK Dr. L. C. Jones (No. 1308, p. 79) has missed the true reason of the unexpanding wings of his moths liberated from the pupa-case before the struggles of the inmate had split the skin, and freed them in the ordinary course.

What was missing to them was the pressure in the act of emergence, which at one and the same time expels a discharge of superfluous humours from the abdomen, and forces the vital fluids through the folded and crumpled wings. Special extra provision is made for this, in the flask-shaped cocoons of *Saturnia Pavonia-minor*, for example, and if the pupa be taken out of this, and allowed to emerge at full maturity, it is always an abortion with heavy, overloaded abdomen, and wings that never expand. Every collector, also, who has bred the earth-burying sphinxes—*Sphinx Ligustri*, for example—knows how often they emerge in this condition, either through not being supplied with soil of the needful tenacity, or from the difficulty of keeping it of the natural degree of moisture.

It would be rash to assume that the struggles of parturition have no analogous bearing on the after vigour and welfare of offspring in the mammalid also. HENRY CECIL.

Bregner, Bournemouth, November 27.

Snakes "Playing 'Possum."

IN connection with Dr. L. C. Jones' account last week of the Puffing Adder that feigned death, it may be of interest to note that on several occasions I have observed similar behaviour on the part of the English grass-snake (*Coluber natrix*). On finding escape impossible the animal would roll slightly over, with its mouth open to its widest extent, and its tongue protruded, and remain perfectly limp and flaccid, allowing itself to be stroked, moved, and even carried in the hand with the head and tail dangling down on opposite sides, without showing any signs of animation. So sudden is the change from activity to quiescence, and so admirable the imitation of lifelessness that it presents, that on the first occasion on which I witnessed it (now many years ago), I believed the snake to have been seized by some species of fit, and to be at the point of death until, in the faint hope of alleviating its seemingly desperate condition, I plunged it into some cold water, with the happy result of effecting its immediate restoration, the snake possibly thinking its ruse had been successful, and it was once more free. I have known cases, however, in which the symptoms have persisted after the application of the cold-water cure. Subsequently I discovered that no treatment of any kind was necessary, as the snake would "come to" of its own accord after a while.

A point which I should be very interested to learn is whether this condition is produced voluntarily by the animal for protective purposes, "the same with intent to deceive," or is the result of a general nervous inhibition, produced reflexly by the action of fright, which would render it more or less analogous to a fainting-fit. G. E. HADOW.

VOLCANIC STALACTITES.

A CURIOUS formation is described by Mr. E. Goldsmith in the *Proceedings* of the Philadelphia Academy of Natural Sciences (part i. 1894, p. 107). It is well known that the highly heated and very fluid lava in the Kilauea crater at Hawaii, as well as in other craters, is occasionally shot up into the air some thirty feet or more. This lava in its descent through the air becomes very porous. If such a highly porous rock have a space underneath, a fresh deposit of liquid lava will trickle through the porous cooled lava, forming as it solidifies the pendant stalactites shown in the accompanying picture, which illustrates Mr. Goldsmith's paper, and has been kindly sent to us by the Academy. The figure represents the entrance to a volcanic cave, photographed by Profs. Sharp and Libbey. It shows an overhanging roof of porous basalt, from which are suspended irregularly gnarled rods of volcanic stalactites; on the floor are scattered fantastic-shaped volcanic stalagmites, which seem to be much thicker than the pendant rods above. Mr. Goldsmith says that the stalactites are about one-fourth of an inch thick, and about eight inches long. They show no disposition to form cones like those seen in limestone caves. They are mostly hollow and porous, and very brittle. The colour is usually a deep black, but sometimes a part is of a brownish tint, due, Mr. Goldsmith thinks, to a higher oxidation of the magnetite present. Fragments of the stalactites, when microscopically examined, exhibited a glassy felspar having apparently the characteristic of sanidine. Magnetite occurred in great profusion, and also gases, probably air. Augite was suspected, but not definitely determined. The specific gravity of a coarse

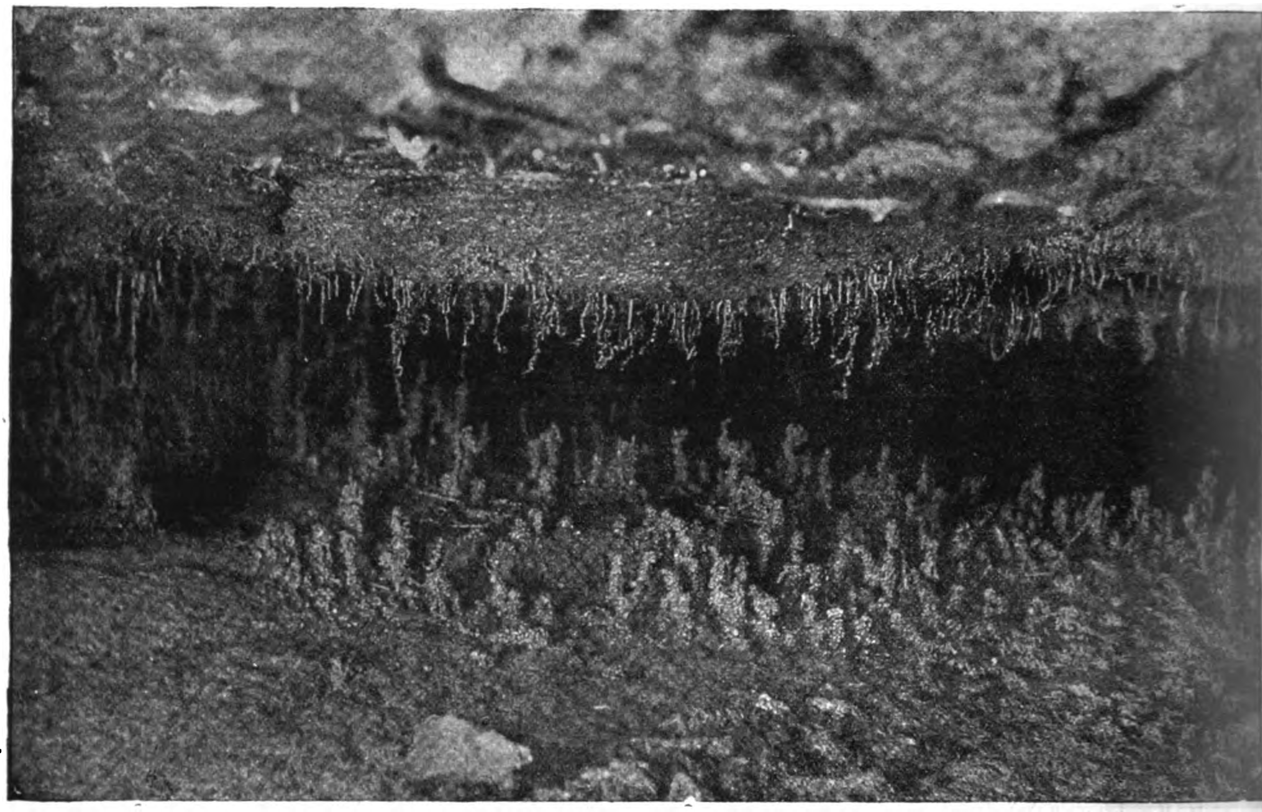

FIG. 1.—Volcanic Stalactites and Stalagmites.

powder produced from the stalactites was found to be 2·85. The lava is decidedly basic, as the quantity of silica determined analytically was 48·55 per cent. On some of the stalactites a thin layer of colourless crystals were recognised under the microscope. An examination of these incrusting crystals proved them to be selenite.

NOTES.

WE are pleased to note that the Court of the Salters' Company have placed at the disposal of the City and Guilds of London Institute a grant of £150 a year, for founding one or more Fellowships for the encouragement of higher research in chemistry in its relation to manufactures. The Fellowships will be awarded by the Executive Committee of the Institute, and the amount of the grant attached to each will be determined by the Committee, with reference to the nature of the research, the time required to complete it, and the merits of the candidate. The Executive Committee will each year apply the sum provided by the Salters' Company to the award of Fellowships to British-born subjects, of a value not exceeding £150 (*a*) to students of the Institute who have completed a full three-years' course of instruction in the chemical department of the Central Technical College, or (*b*) to candidates duly qualified in the methods of chemical research in its relation to manufactures, without restriction as to age or place of previous study. A Fellowship may be renewed for a second and third year, but cannot be held by anyone for more than three years. The holders of the Fellowships will be required to devote their whole time to the prosecution of research, unless otherwise sanctioned by the Executive Committee. The researches will be carried out at the Institute's Central Technical College. Applications for Fellowships should be made in writing addressed to the Honorary Secretary of the Institute, Gresham College, Basinghall Street, London, E.C., and should state the nature of the research proposed to be undertaken, and the qualifications of the candidate. The first award will be made early in the new year.

WE notice with deep regret that Sir Charles T. Newton, K.C.B., the eminent archæologist, died on November 28.

COMMUNICATION by telephone between Vienna and Berlin has just been opened. The length of the line is 410 miles.

DR. S. NAWASCHIN has been appointed Professor of Botany and Director of the Botanic Garden at the University of Kiew; and Dr. K. Schilbersky Professor of Botany and Vegetable Pathology at the Hungarian Agricultural Institute, Buda-Pesth.

THE editorship of the *Jahrbücher für wissenschaftliche Botanik*, vacant by the death of Dr. Pringsheim, has been accepted by Prof. Pfeffer, of Leipzig, and Prof. Strasburger, of Bonn. All communications should be addressed to the former of these. The *Jahrbücher* have been edited by Dr. Pringsheim since their commencement in 1857, and contain many important contributions to structural and physiological botany.

DR. PHILIP LENARD, who was the late Prof. Hertz's assistant and *privat-docent* at the University of Bonn, has recently been appointed Extraordinary Professor of Physics in the University of Breslau. He has published a number of important investigations on cathode rays, phosphorescence, electrification of water-drops, and kindred subjects.

THE Council of the British Institute of Public Health, realising the great and general interest which is at the present time taken in the question of the anti-toxic serum treatment of diphtheria, have made arrangements for a lecture to be given in the Examination Hall of the Royal Colleges of Physicians and Surgeons, Victoria Embankment, on Friday, December 7, at 5 p.m. by Dr. G. Sims Woodhead, entitled "The Diagnosis and Anti-toxic Treatment of Diphtheria."

THE second series of lectures given by the Sunday Lecture Society begins on Sunday afternoon, December 9, in St. George's Hall, Langham Place, at 4 p.m., when Mr. E. Neville Rolfe will lecture on "The Buried Cities of Campania." Lectures will be subsequently given by Mr. Wyke Bayliss, Prof. Marshall Ward, F.R.S., Prof. Vivian B. Lewes, Mr. Oswald Brown, Mr. Arthur Clayden, and Mr. Jas. Craven.

THE following lecture arrangements have been made at the Royal Institution: Prof. J. A. Fleming, F.R.S., six lectures (adapted to a juvenile auditory) on the work of an electric current; Prof. Charles Stewart, twelve lectures on the internal framework of plants and animals; Mr. L. Fletcher, F.R.S., three lectures on meteorites; Dr. E. B. Tylor, F.R.S., two lectures on animism; Lord Rayleigh will also deliver six lectures. The Friday evening meetings will commence on January 18, when Prof. Dewar will deliver a discourse on phosphorescence and photographic action at the temperature of boiling liquid air. Succeeding discourses will probably be given by Sir Colin Scott-Moncrieff, Dr. G. Sims Woodhead, Mr. Clinton T. Dent, Prof. A. Schuster, Prof. A. W. Rücker, Prof. Roberts-Austen, Prof. H. E, Armstrong, and Lord Rayleigh, among others.

DR. PATTERSON, in a lecture before the Piscatorial Society, at the Holborn Restaurant this week, entitled "Salmon, Sea-trout, and Trout—What are they?" maintained that they were all varieties of one species, varying according to their environments. On the same evening an exhibition of this year's specimen fish was held by this Society in their museum at the Holborn.

AT a meeting held at the Borough Road Polytechnic, on November 23, a London branch of the Conchological Society of Great Britain and Ireland was formed. It is thought that such a branch, with monthly meetings for discussion, for exhibition, and for exchange, cannot fail to be of advantage. The branch will in no way be a rival of the Malacological Society, but probably a feeder to it. The first ordinary meeting will be held on Thursday, January 10, 1895, at 7 p.m., in a room lent by the Governors of the Borough Road Polytechnic. The attendance of any conchologists in or near London will be welcomed at this meeting.

DURING the past few years the American Museum of Natural History, situated in Central Park, New York City, has grown very considerably. It suffers from the common complaint, however, of not having sufficient funds to devote to the enlargement of the collections, and this in a city where millionaires most do congregate. The report of the operations of the Institution last year shows that the opening of the museum on Sundays is greatly appreciated. Many important additions have been made to the various collections, the most noteworthy accessions being in the department of mammalian palæontology. Although only in the third year of its establishment, the collections in this department already equal in importance those secured by other institutions through many years of effort. The intention is to form a great collection to represent the evolution of the mammals of North America. Thus far the expeditions to the Rocky Mountain region have secured nearly one thousand five hundred specimens. Fifteen perfect skulls have been obtained from the Bridger Basin, Wyoming. The remains of monkeys, horses, tapirs, primitive rhinoceroses and rodents have also been obtained by the explorations under Dr. J. L. Wortman, and many of them are in an excellent state of preservation. The most notable specimen in the collection is a complete skeleton of a large Carnivore of the size of a tiger, and is said to be the most perfect specimen of the kind ever found. The total number of volumes in the library now exceeds twenty-eight thousand. We sincerely hope that the citizens of New York will see that the usefulness of the Institution is not limited by the lack of means to acquire new and important material, and to provide proper accommodation for it. They must surely recognise that, even from a commercial point of view, the museum is of the highest value.

In connection with our note last week, on the wreck of the *Falcon*, the steamer of the Peary expedition, and the loss of all on board, it ought to have been stated that the vessel, after landing the returning members of Mr. Peary's party, had sailed from St. John's with a cargo of coal, and that none of the exploring party, whose charter of the vessel terminated on their landing, were on board.

In the *Geographical Journal* for December, Captain Mockler Ferryman describes and illustrates the glacier lake known as the Dæmme Vand, near the Hardanger Fiord, in Norway. The Rembesdal glacier at the head of the Simodal, stretches across and dams up a lateral valley in which the lake in question is formed. When during summer the ice-barrier gives way, as it occasionally does, floods of the most disastrous kind are produced in the Simodal. The Norwegian Government has determined to construct a tunnel through the rocks at the mouth of the lateral valley, through which the surplus water of the Dæmme Vand may be harmlessly drained when the level rises to a dangerous height.

Chemical laboratories can now dispense with the wasteful and unpleasant installation for generating sulphuretted hydrogen, for we learn from *Industries and Iron* that liquid sulphuretted hydrogen is commercially obtainable. Although this gas is easily liquefied, the difficulties of manufacture in large quantities at an economic rate have prevented its introduction as a laboratory reagent. Messrs. Baird and Tatlock, who are the sole agents for this commodity, supply the liquid compressed into specially-prepared steel cylinders, each containing one pound of liquid, equal to about eleven cubic feet of gas at atmospheric pressure. Larger cylinders can also be had. In this compressed form, the gas has the advantage of being cleanly and always ready for use, and in those laboratories in which it is only occasionally required as a reagent, a cylinder ought to be included in the laboratory stock. Our contemporary announces that the same firm is about to place liquid chlorine and ethylene on the market.

For collections of Coleopterous, Lepidopterous and other insects, the nature of the pin for fastening the specimens is a question of great importance. Ordinary pins of brass, even though well tinned, frequently oxidise in the body of the insect, and eventually destroy the specimen. Black varnished pins are almost as bad, for the varnish soon cracks, leaving the metal exposed. Even plated pins do not appear to resist the action of the compounds developed in the body of the insect, though solid silver ones will. Dr. H. G. Knaggs introduced a bronze pin which has found favour among many entomologists; nevertheless, it is far from being a perfect fastener. In the December number of the *Entomologist's Monthly Magazine*, he directs attention to a pin made from a nickel alloy by Messrs. Deyrolle, of Paris. This pin possesses great advantages over those generally used, and of which the metal basis is brass. It will probably be widely used by collectors, for its price need only be a little higher than that of an ordinary pin.

That the efficiency of acoustic fog-signals for purposes of navigation is as yet very doubtful, may be seen from a discussion appearing in *Hansa*. There are many peculiarities in the behaviour of sound, propagated over the surface of the sea from the coast, which require further scientific investigation. Mr. Arnold B. Johnson, author of "The Modern Lighthouse Service," gives it as a general rule, that in proceeding from the neighbourhood of the fog-signal apparatus out into the sea for about two miles a zone is entered in which the signal becomes inaudible. This zone has a width varying from one mile to a mile and a half. That this phenomenon is not confined to coast stations is evident from the fact that it was observed in the case of a station situated on a rock twenty miles from the nearest land. Several such zones are often produced when a steep cliff lies at the back of the signal station. The observations made on the coast of New England are fully borne out by those made at the mouths of the Elbe and Weser. Among the pilots of the German coast it is well known that the sound rockets fired on Heligoland are heard at distances sometimes exceeding twenty miles, become inaudible on approaching the island, and reappear in the immediate neighbourhood of the island. An altogether unexplained and apparently undiscussed phenomenon is that noticed in a specially marked manner in the fog-horn of the Weser lightship. When the sound commences it appears to proceed from a direction entirely different from that in which it dies away.

A series of *Bulletins* of the Madras Government Museum has been commenced by the superintendent, Mr. Edgar Thurston; and parts i. and ii., which have reached this country, contain much useful information upon the fisheries and marine zoology of the Presidency. Part i. contains a revised account of the superintendent's "Notes on the Pearl and Chank Fisheries of the Gulf of Manaar," and its subject matter is already known in great part to British students of "applied zoology." Part. ii., entitled "Note on Tours along the Malabar Coast," records a number of interesting observations in marine zoology made on the west coast of Madras. It is instructive to note that even there the natives have their fishery question. It is stated that formerly the sardines of the coast always arrived regularly, and remained throughout the season; and the fishermen's belief is that they are at the present day frightened away by the numerous steamers which call at Cochin, and retire in search of a less disturbed spot. In addition to steamboat traffic; noises in boats, ringing church bells, artillery practice, the erection of lighthouses, gutting fish at sea, using fish as manure, burning kelp, and the wickedness of the people, have been charged with being responsible for a falling off of the fish supply; but, as Mr. C. E. Fryer has naïvely remarked, "of these alleged causes only the last, it is to be feared, has been, and is likely to be, a permanent factor in the case."

We have received from the Rev. S. Chevalier, the second report of the Shanghai Meteorological Society. This number is entirely devoted to a notice of the typhoons of the year 1893, and a final chapter on the general tracks of the typhoons in the Chinese seas. The discussion of each storm is accompanied by diagrams showing the position of the centre at various dates; several examples reported in the present work show that the bearing of the centre coincides with the direction of the swell of the sea, but further observations on that special point are required. The tracks of the typhoons have been classed (1) according to the times of their occurrence, and (2) according to the countries which they visit. The first month of the typhoon season is May, but the storms are of rare occurrence before July; it is noticeable that they originate in different positions, and take somewhat different routes in different months. From the middle of September the typhoons do not reach Shanghai, but they occur further south for some months later. In dividing them according to localities, Father Chevalier distinguishes three classes, viz. Japan typhoons, China, and Cochin China typhoons.

THE *Report* of the Botanical Exchange Club of the British Isles for 1893, just received, contains a number of useful and interesting notes on critical and rare British species, the general *Rubus*, *Hieracium*, and *Potamogeton* coming in for a specially large share of attention. It is edited by Mr. Jas. Groves.

THE results of the meteorological observations made at the United States Naval Observatory during 1889, and the magnetic observations made at the same observatory during 1892, have just reached us. It would be to the advantage of science if the observations could be published without such a long delay.

THE twenty-first annual report of the Geological and Natural History Survey of Minnesota has been received. It embraces statements relating to progress in the strictly geological portion of the Survey. Independent reports will be published upon the botanical and zoological departments of the work.

THE December number of the *Geological Magazine* contains an account of the life and work of the late Mr. William Topley, F.R.S., written by Mr. H. B. Woodward, and accompanied by a portrait of the deceased geologist. The memoir is a tribute to a life of unremitting labour in the cause of geology, and an expression of the high regard in which Mr. Topley is held by all who cherish his memory.

THE *Geographical Journal* this month gives prominence to a new feature in the way of short summaries of the most recent and trustworthy literature on parts of the world where public interest is concentrated for the time. The regions dealt with are the Waziri country and Madagascar, and in addition there are two special papers of considerable length on Eastern Asia—one by Mr. A. R. Agassiz, on the commercial resources of Manchuria; the other by Baron von Richthofen, on China, Japan, and Korea.

HITHERTO Brehm's well-known collection of works on natural history, in the Merveilles de la Nature series, published by MM. J. B. Baillière et Fils, Paris, has not comprised a volume on botany. This gap is now, however, to be filled by "Le Monde des Plantes," of which the first part has just appeared. The author of the work is Prof. Paul Constantin. There will be eight fasciculi altogether. When the work is completed its two volumes will run into fifteen hundred pages, and be embellished by two thousand illustrations. Particular attention is paid to the use of plants for food, and in medicine, industries, agriculture, and horticulture. The biological characters are also carefully treated. The work promises to be the best popular botanical work published in France, and therefore fittingly finds a place in Brehm's series on the wonders of nature.

MR. A. S. GHOSH has sent us a slender little pamphlet on "Pedal and Antipedal Triangles," being an attempt to investigate the laws of their evolution. (Calcutta: Patrick Press, 1894.) The primitive triangle is considered as obtained from the pedal triangle, and is called its antipedal triangle; so that what is sometimes called the excentric triangle is the antipedal of the primitive triangle. The whole of the pamphlet, which is a fairly neat piece of work, is merely a solution *in extenso* of a "ten-minute conundrum."

WE have received the *Proceedings* and *Transactions* of the Royal Society of Canada, for the year 1892 (vol. x.). The volume contains six papers in the section of mathematical, physical, and chemical sciences. Among these we notice one on the Mexican type in the crystallisation of the topaz, and another on observations of sun-spots at the McGill College Observatory. The section of geological and biological sciences contains the presidential address on the diffusion and sequence of the Cambrian faunas; and, among others, papers on the artificial propagation of marine food fishes and edible crustaceans, and on the correlation of early cretaceous floras in Canada and the United States.

AT the inaugural meeting of the fourteenth session of the Institution of Junior Engineers, held on November 16, Mr. Alexander Siemens gave some wholesome advice to young engineers and inventors. In the course of his address, he dispelled the fable about the circumstances which led to the invention of the steam engine. According to the popular version, Watt, as a small boy, saw the lid of a tea-kettle move up and down, when the water was boiling, and this suggested to him the construction of the steam engine. As a matter of fact, Watt made himself acquainted with what had been done before (a point altogether ignored in the popular version), and had to work very hard before he brought his invention to a successful issue. His example is typical of the true method of progress, and it may be said generally, that in order to approach a problem with the best prospect of success, it is necessary (1) to define, as accurately as possible, the want that exists, or the particular object that is to be attained; (2) to be well acquainted with the scientific principles which come into play; (3) to know how the want is met, or the object attained in practical life; (4) to find out what proposals have been made by others in the same or in a similar case. A careful attention to these requirements will prevent much disappointment and waste of energy. The records of the Patent Office show that one or more of these conditions is frequently ignored. A large class of inventors do not realise that a knowledge of scientific principles would be an assistance in their efforts; or if they study science at all, they think they can acquire the necessary knowledge by a short study, and without much trouble.

A NOTE concerning the synthesis of the chlorides of carbon C_2Cl_4 and C_2Cl_6, during the preparation of carbon tetrachloride by the chlorination of carbon disulphide at low temperatures, is communicated to the *Berichte* by Prof. Victor Meyer. It is a well-known fact that at a red heat the vapour of carbon tetrachloride is dissociated, a portion of the chlorine being liberated and the two chlorides above mentioned being produced. It now appears that this change occurs to some extent at temperatures but slightly elevated above the ordinary. At the chemical works of Messrs. Müller and Dubois, near Mannheim, carbon tetrachloride is manufactured in large quantities by the chlorination of carbon disulphide at temperatures between 20° and 40°. Each operation is allowed to proceed for several days, and the completion is indicated when the liquid has become deeply coloured owing to the formation of sulphur dichloride, S_2Cl_2. The carbon tetrachloride is then distilled off, leaving the chloride of sulphur behind. Upon rectification of the carbon tetrachloride a quantity of a higher boiling oil is obtained, the nature of which Prof. Meyer has investigated. Upon fractionation it separates into three constituents, carbon tetrachloride CCl_4, the liquid chloride analogous to ethylene C_2Cl_4, and the solid chloride C_2Cl_6, the so-called perchlorethane. Excellent crystals of the latter compound are at once obtained practically pure. That a real synthesis of these two latter compounds occurs during the manufacture of carbon tetrachloride at so low a temperature as 20°–40°, is proved by the fact that the carbon disulphide employed is found to be quite pure, except for a mere trace of dissolved free sulphur. Prof. Meyer considers that the two chlorides are produced in accordance with the equations:

$$2CS_2 + 10Cl = C_2Cl_6 + 2S_2Cl_2,$$
$$2CS_2 + 8Cl = C_2Cl_4 + 2S_2Cl_2.$$

THE atomic weight of bismuth has been re-determined by Prof. Schneider, of Berlin, and the result is remarkable as once more affording exactly a whole number, 208, as the relative weight of an elementary atom compared with the atom of hydrogen. The relative weight of this particularly heavy atom was determined so long as forty-three years ago by Prof. Schneider, and the value obtained was identical with that which is now afforded. Eight years after Prof. Schneider's first determination, Dumas published the results of a number of atomic weight determinations, among them being that of bismuth, to which he assigned the value 210. From that time, 1859, until 1883, Dumas' value came to be generally accepted, although no doubt his method was by no means so little open to objection as that employed by Prof. Schneider. However, in 1883 Marignac took up the subject, and as the result of determinations carried out with the thoroughness for which he was remarkable, the number 208·16 was obtained, thus substantiating the work of Prof. Schneider. More recently Classen has obtained a higher result, 208·9, by an electrolytic method, and Prof. Schneider has undertaken a further series of determinations with the view of testing certain suggestions of Prof. Classen regarding possibility of error in his former estimations. The method is based upon a comparison of the equivalent relation of metallic bismuth to bismuth trioxide. The final result obtained, if O = 16, is 208·05, and the greatest divergence from this number among the whole of the individual values is only 0·21. Prof. Schneider's original work, and likewise that of Marignac, is thus confirmed, and bismuth must now be added to the rapidly growing list of elements whose atomic weights are represented by whole numbers.

THE additions to the Zoological Society's Gardens during the past week include a Sykes's Monkey (*Cercopithecus albigularis*, ♂) from West Africa, presented by Mr. J. H. Prestwich; a Mozambique Monkey (*Cercopithecus pygerythrus*, ♂) from East Africa, presented by Mr. C. O. Gridley; a Leopard (*Felis pardus*) from Southern India, presented by Mr. John Christie; two Spotted Eagle Owls (*Bubo maculosa*) from South Africa, presented by Mr. R. A. Langford; an Antipodes Island Parrakeet (*Cyanorhamphus unicolor*) from Antipodes Island, seven South Island Thrushes (*Turnagra crassirostris*) from South Island, New Zealand, presented by Sir Walter L. Buller; two Canary Finches (*Serinus canarius*), four —— Frogs (*Rana*, sp. inc.) from Madeira, four Dwarf Chameleons, (*Chamæleon pumilus*) from South Africa, presented by Mr. H. Bendelack; a Rhomb-marked Snake (*Psammophylax rhombeatus*) from South Africa, presented by Mr. J. E. Matcham; an Arctic Fox (*Canis lagopus*) from the Arctic Regions, deposited; four Nutcrackers (*Nucifraga caryocactes*), European, purchased; sixteen Deadly Snakes (*Trigonocephalus atrox*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE NEW COMET.—The comet of which the discovery was announced in the last number of NATURE is likely to prove a very interesting object. A communication from Prof. Krueger informs us that Dr. Berberich, who is probably in possession of ephemerides of the lost comets depending on various dates of perihelion passage, has noticed the coincidence in the position of this comet at the first observation with that which De Vico's comet of 1844 can assume. It will be remembered that it was this same astronomer who conjectured from somewhat similar grounds the identity of Holmes' comet with that of Biela. But the conjecture in this case seems to be better founded, for elements computed by Dr. Leuschner show a decided similarity with those of De Vico, as computed by the late Dr. Brunnow from the 1844 observations. Seeing that the comet has undergone some fifty years' perturbations since that time, and that the present elements are founded on the observations of but three consecutive days, and can only be considered as roughly approximate, we must be prepared for some considerable deviation.

		Leuschner's elements of Swift's comet.		Brunnow's elements of De Vico's comet.

De Vico's comet has not been seen since 1844, though, with a period of approximately five and a half years, nine returns have occurred, and when the perihelia fall in the autumn, the comet is fairly favourable for observation. There is extant, it is true, an observation of a nebula by Goldschmidt in May 1855, which he thought might have reference to the comet, but Brunnow could not reconcile it with the computed path, and it is usually believed that the comet disappeared after observation in 1844. But Le Verrier and Brunnow both thought that the comet of 1678 was identical with that of 1844, and if this be the case it would seem that the comet might be subject to fluctuations of brilliancy, which would explain the fact of its passage through perihelion without notice.

Further, a similarity between the elements of Finlay (1886 VII.) and De Vico has been noticed, and the agreement between those of the present comet and Finlay's is probably more marked than with De Vico. Tisserand's well-known criterion of identity does not favour the supposition that De Vico and Finlay are one and the same comet, since a very considerable perturbative effect would have to be attributed to the action of Mars. It would seem, therefore, more probable that several comets are moving in approximately the same orbits than that we have to do with the actual return of a comet lost for so long a period as De Vico's. But under any circumstances, seeing that the comet is diminishing in brilliancy, it is of the utmost importance to secure observations as early and as long as possible, since upon the accurate determination of the orbit several important questions may finally rest. The following positions are given in the ephemeris received from Kiel:—

THE SPECTRUM OF MARS.—Prof. W. W. Campbell has lately brought together all the observations of the spectrum of Mars, and discussed them in connection with the telluric spectrum and with his own observations made during the past summer. (*Publications of the Astronomical Society of the Pacific*, vol. vi. No. 37.) He concludes as follows:—

(1) The spectra of Mars and the Moon, observed under favourable and identical circumstances, seem to be identical in every respect. The atmospheric and aqueous vapour bands which were observed in both spectra appear to be produced wholly by the elements of the Earth's atmosphere. The observations, therefore, furnish no evidence whatever of a Martian atmosphere containing aqueous vapour.

(2) The observations do not prove that Mars has no atmosphere similar to our own; but they set a superior limit to the extent of such an atmosphere. Sunlight coming to the Earth *via* Mars passes twice either partially or completely through his atmosphere. If an increase of 25 to 50 per cent. in the thickness of our own atmosphere produces an appreciable effect, a possible Martian atmosphere one fourth as extensive as our own ought to be detected by the method employed.

(3) If Mars has an atmosphere of appreciable extent, its absorptive effect should be noticeable especially at the limb of the planet. Prof. Campbell's observations do not show an increased absorption at the limb. This portion of the investigation greatly strengthens the view that Mars has not an extensive atmosphere.

THE ANNIVERSARY MEETING OF THE ROYAL SOCIETY.

THE anniversary meeting of the Royal Society was held in the apartments of the Society at Burlington House on St. Andrew's Day, November 30. The auditors of the Treasurer's accounts having presented their report, the Secretary read the lists of Fellows elected and deceased since the last anniversary meeting. The qualification of the new Fellows on the home list were given in NATURE of May 17 (vol. l. p. 55). The new Fellows on the foreign list are Henri Ernest Baillon, Henri Poincaré, and Eduard Suess. During the year, the Society lost eighteen Fellows and three Foreign Members.

H.R.H. Louis Phillippe d'Orleans, Count of Paris, September 8, 1894, aged 56.
John Tyndall, December 4, 1893, aged 73.
The Earl of Lovelace, December 29, 1893, aged 89.
Sir Samuel White Baker, December 30, 1893, aged 72.
Arthur Milnes Marshall, December 31, 1893, aged 41.
Pierre J. Van Beneden, January 8, 1894, aged 93.
William Pengelly, March 16, 1894, aged 82.
Lord Hannen, March 29, 1894, aged 73.
Dr. Charles Edouard Brown-Séquard, April 1, 1894, aged 77.
Lord Bowen, April 10, 1894, aged 58.
Brian Houghton Hodgson, May 23, 1894, aged 94.
George John Romanes, May 23, 1894, aged 46.
Lord Coleridge, June 5, 1894, aged 74.
Charles R. Alder Wright, July 25, 1894, aged 50.
Rev. William Bentinck Latham Hawkins, August 31, 1894, aged 83.
Admiral Sir Edward Augustus Inglefield, September 5, 1894, aged 74.
Hermann Ludwig Ferdinand von Helmholtz, September 8, 1894, aged 73.
Jean Charles Galissard de Marignac, September 15, 1894, aged 77.
William Topley, October 2, 1894, aged 53.
Lord Basing, October 22, 1894, aged 68.
Colonel R. Y. Armstrong, November 1, 1894, aged 55.

Lord Kelvin, the President, then delivered the Anniversary Address as follows:—

Science has lost severely during the past year. In the list of Fellows deceased, which I have read to you, you have heard the names of Tyndall, Milnes Marshall, Van Beneden, Pengelly, Brown-Séquard, Romanes, Alder Wright, Helmholtz, Marignac, Topley, all well known to you as having been in their lives zealous and successful scientific investigators, who have largely contributed to the object for which the Royal Society works, "The Increase of Natural Knowledge." Tyndall, full of fire and enthusiasm in solid experimental work advancing the boundaries of science, contributed largely, by his brilliant lectures and books, to make science popular, as it now is in England and America. By the sad death of Milnes Marshall on Scawfell, in Cumberland, on the last day of 1893, we lost a young, able, and enthusiastic worker in zoology. A few months later, we lost the veteran Pengelly, who did so much for geological science, and gave such delightful and valuable lessons to the larger world of not scientific geologists, in what he did in his exploration of Kent's Cavern, Torquay. Romanes, full of zeal, fighting to the end with the most difficult problems that have ever occupied the mind of man, and devoting his health and his wealth to promote not merely philosophical speculation but also the experimental research by which alone philosophy can have a foundation, left us at the early age of forty-six.

A year ago, in my anniversary address, I called your attention to Hertz's experimental demonstration of electric waves, which he found in working out an experimental problem originally proposed by Helmholtz to him when he was engaged in experimental researches in the Physical Institute of Berlin in 1879. An English translation by Jones, of Hertz's book describing his work on electric waves, dedicated "with gratitude" to Helmholtz, was published in England and America in December 1893. On the first day of the new year the disciple died, and within the year the master followed him. Of the whole of Helmholtz's great and splendid work in physiology, physics, and mathematics, I doubt whether any one man may be qualified to speak with the power which knowledge and understanding can give: but we can all appreciate, to some degree, the vast services which he has rendered to biology by the application of his mathematical genius and highly trained capacity for experimental research to physiological investigation.

In his interesting autobiographical sketch he tells us that his early natural inclination was for physics, which he found more attractive than purely geometrical and algebraic studies; but his father could only give him the opportunity of studying physics by his learning medicine to earn a livelihood, and he himself was by no means averse to thus entering on the study of living matter instead of confining himself to the physics of dead matter. I think we may now feel that the world has gained largely by this early necessity for a young man of great genius and power to choose a practical profession.

One early result was his careful examination, while still a student, of the theory of animal heat, and a little later (1847) his great essay, "Ueber die Erhaltung der Kraft," Conservation of Energy as we now call it, communicated to the Society of Berlin on July, 3 1847, of which he said in 1891, "My aim was merely to give a critical investigation and arrangement of the facts for the benefit of physiologists." As a student he had found that Stahl's theory, ascribing to every living body the possession of the property of "The Perpetual Motion" as an essence of its "vital force," was still held by most physiologists." His essay on the "Conservation of Energy," giving strong reasons for rejecting that theory, though looked upon, at first, by many of the physical and philosophical authorities of the time as a fantastic speculation, was enthusiastically welcomed by younger student philosophers, and must soon have convinced the elder men that, whatever may be the real efficiency of vitality, vast and wonderful as it is, it does *not* include the performance of work without drawing upon a source of energy. This conclusion had been virtually foreseen before the end of last century by Rumford and Davy, and had been clearly stated and powerfully supported by Joule and Mayer a few years before Helmholtz found it for himself and successfully persuaded others of its truth.

It is interesting for us now to know that, while thus contributing so effectively to the abandonment of the old doctrine that vital "force" can work without drawing on an external source of energy, Helmholtz was even more effectively concerned in the establishment of a new doctrine which has given a vast extension to the province of life previously perhaps undreamt of, but now universally recognised as thoroughly well established, and supremely important in modern physiology and medicine. On recovering from a typhus fever in the autumn of 1841, at the age of twenty, the last year of his undergraduate course in the Army Medical School of the Friederich Wilhelm's Institute, he spent the accumulations of his income, which free treatment at the hospital during his illness had left him, in the purchase of a microscope, an instrument then but little used in medical education. He began immediately to use it, and made some important observations on the ganglion cells of invertebrates, which, at the suggestion of his master, Johannes Müller, he took as the subject of his inaugural thesis for the doctor's degree, in November 1842, and which was his first published work.[1] With the same microscope, he observed vibrios in putrefying liquids, which he described in his second published paper (1843), "On the Nature of Putrefaction and Fermentation." His distinguished comrade, Schwann, in the laboratory of Johannes Müller, had already shown that vegetable cells are present in fermenting solutions of sugar, and that air, which had been highly heated, was incapable of exciting the fermentation which the access of ordinary atmospheric air was known to produce. Helmholtz found that oxygen, yielded by the decomposition of water in flasks containing small pieces of boiled meat, did not produce putrefaction. Thus the doctrine, held perhaps by all before them, and certainly supported by the great Liebig, that putrefaction and fermentation are purely chemical processes of eremacausis (or slow combustion), produced by oxygen, was thoroughly disproved by the two young investigators. But Helmholtz went farther, and showed almost certainly that the actual presence of a living creature, vibrio, as he called it, bacterium, as we more commonly call it now, is necessary for either fermentation or putrefaction. He proved by experiment that a partition of moist bladder, between the yeast and the fermentable liquid, prevented the entrance of the vibrios which he had observed, *and prevented the fermentation.* It had been reasonably suggested that fermentation or putrefaction might be a purely chemical process produced by a quasi-chemical agent or poison secreted by a living organism; but Helmholtz's observation disproved this supposition almost certainly, because any such chemical substance in solution would pass by diffusion through the bladder, and produce its effect without any direct action of the living creatures. Although Helmholtz himself was characteristically philosophical and conscientious in not claiming, as absolutely proved, what he had only rendered probable, it is certain that this early work of his on putrefaction and fermentation constituted a very long step towards the great generalisa-

[1] Helmholtz's "Wissenschaftliche Abhandlungen," vol. ii. p. 663

tion of Pasteur, adverse to spontaneous generation, and decisive in attributing to living creatures, born from previous living creatures, not only fermentation and putrefaction, but a vast array of the virulent diseases and blights, which had been most destructive to men, and the lower animals and crops and fruits. It is well that Helmholtz himself lived to see the great benefits conferred on mankind by Pasteur's work; and by the annulment of the deadliness of compound fractures and the abolition of hospital gangrene in virtue of Lister's antiseptic treatment; and by the sanitary defences against fevers and blights, realised by many other distinguished men as practical applications of the science which his own typhus fever of 1841 helped so much to create.

Close after his work on this subject and on animal heat, followed investigations on the velocity of transmission along the sensory nerves of the disturbance to which sensation is due, the time which the person perceiving the sensation takes to decide what to do in consequence, and the velocity of transmission of his orders along the motor nerves to the muscles which are to carry out his will. Results of the highest scientific interest and of large practical importance were given in two great papers published in 1850.[1] This was followed a few years later by his "Tonempfindungen," a great work not merely confined to the perception of sound, but including mathematical and experimental investigations on the inanimate external influences concerned in sound, investigation of the anatomical structure of the ear in virtue of which it perceives sound, and applications to the philosophical foundation of the musical art; which holds a unique position in the literature of philosophy, and is certainly a splendid monument to the genius and indomitable working power of its author. Another great work of Helmholtz is his "Physiologische Optik"; who shall say which of the two books is the more important, the more interesting, or the more valuable? Each of them has all these qualities to a wonderfully high degree. Perhaps the most interesting of his experimental investigations in physiological optics was the measurements, by his ophthalmometer, of the curvatures of the several refracting surfaces constituting the lens-system of the eye, from which he ascertained that it is almost altogether by changing the curvature of the front surface of the crystalline lens that the eye is accommodated by its possessor to vision at different distances. His ophthalmoscope, by which for the first time he himself saw and showed to others the retina of the living eye, was a splendid and precious contribution to medicine. By allowing that outlying portion of the brain to be distinctly seen and examined, it has shown the cause of many illnesses which had been regarded as hopelessly obscure; and for diagnosis and guidance of medical treatment, it is now continually used not only by oculists, but by general practitioners.

Constrained as I feel not to overtax your patience, I find it impossible, on the present occasion, to enter upon Helmholtz's researches in mathematics and mathematical physics farther than just to mention his small but exquisite paper on anomalous dispersion, and the grand contribution to hydrodynamics which we have in his "Integrals of the Hydrodynamical Equations which express Vortex Motion."[2]

Since our last anniversary, important questions regarding the conduct of the ordinary meetings and the publication of papers, both in the *Transactions* and *Proceedings* of the Royal Society, have been engaging the attention of the Council, with the assistance of a committee appointed on July 5, 1893. The final report of this committee was submitted to the Council on July 5, 1894, when resolutions were adopted accepting some of its recommendations and deferring the consideration of others until after the recess.

At the request of the Royal Geographical Society, a committee was appointed by the Council of the Royal Society to consider the advisability of asking the Government to undertake an Antarctic expedition. A very important and valuable report on the advantages which such an expedition would bring, both to science and to practical navigation, was presented by this committee to the Council on May 24. The Council, after much careful consideration, resolved to ask the Lords of the Admiralty to grant an interview on the subject with representatives of the Royal Society. This request was assented to: and an interview was accordingly held between the First Lord of the Admiralty and representatives of the Royal Society; but the proposal of an Antarctic expedition was not favourably received.

[1] Helmholtz's "Wissenschaftliche Abhandlungen," p. 763-861.

[2] *Philosophical Magazine*, July 1867, being the translation by Tait of the original German paper, which appeared in *Crelle's Journal* in 1858, and which has been republished in "Wissenschaftliche Abhandlungen," vol i. pp. 101 134.

The Joule Fund Committee submitted its report on December 7, 1893, and the Council, on its recommendation, adopted the following resolutions:—

I. That the regulations for administering the Joule-Memorial Fund be as follows:—

(1) That the proceeds be applied in the form of a studentship or grant, to be awarded every year, to assist research, especially among younger men, in those branches of physical science more immediately connected with Joule's work.

(2) That this grant be international in its character, and awarded alternately in Great Britain and abroad, or in such order as the President and Council shall from time to time decide.

(3) That it be awarded in Great Britain by the President and Council of the Royal Society; and, for award in France, offered to the Académie des Sciences, Paris; and in Germany to the K. Akademie der Wissenschaften, Berlin; or, in any other country, to the leading scientific institution, for award in that country.

(4) That the award in Great Britain be made on the recommendation of a committee, from time to time appointed by the President and Council of the Royal Society, but not of necessity confined to Fellows of the Society.

II. That a sum of £100, which is now, or shortly will be, available, for the first studentship or grant be awarded in accordance with Regulation 4.

The first appointment was accordingly made on June 21, 1894, when it was resolved:—

(1) "That a Joule Scholarship of the Royal Society Memorial Fund be awarded to Mr J. D. Chorlton, of Owens College, Manchester, for the purpose of enabling him to carry on certain researches on lines laid down by Dr. Joule, more especially with the view of determining the constants of some of the instruments employed by Dr. Joule, which can be placed at his disposal by his representatives."

(2) "That the value of the Scholarship be £100, payable quarterly, on the certificate from the authorities of Owens College that the researches are being conducted in a satisfactory manner."

On the occasion of Sir George Buchanan's retirement from the post of Chief Medical Officer to the Local Government Board, it was decided by some of his friends that a testimonial should be presented to him, and a sum, amounting to about £340, has been subscribed by medical officers of health, sanitary engineers, and others interested in sanitary science. It was resolved, on the suggestion of Sir George Buchanan himself, that this testimonial should take the form of a medal, to be awarded periodically for work done in connection with sanitary science, and that the Royal Society should be asked to administer the testimonial fund under the following conditions:—

(1) The money collected, after paying expenses incurred, to be devoted—

(*a*) To the foundation of a Gold Medal of the value as nearly as may be of twenty guineas, with a portrait of Sir George Buchanan on the one side and an appropriate design on the other, to be awarded every three or five years in respect of distinguished services to Hygienic Science or Practice, in the direction either of original research or of professional, administrative, or constructive work.

(*b*) To the bestowal on the recipient of the Medal of the amount (remaining after paying for the Medal and discharging the incidental expenses) which has accumulated since the last award.

(2) The Medal to be awarded without limit of nationality or sex.

The Council of the Royal Society has accepted the trust under these conditions; and it was agreed that the first medal should be given to Lady Buchanan by the testimonialists themselves.

The Catalogue Department has been specially active in the past session. Mr. Ludwig Mond's generous gift of £2000, which I announced to the Society in my anniversary address last year, has given a new impulse to our operations in that department, and enabled us to increase the staff of assistants. Under the able superintendence of Miss Chambers, volume 10 of the Catalogue under authors' names has been completed, and was issued in June of the present year. The Society is indebted to several members of the Catalogue Committee who have lent their scientific knowledge to aid in the revision of the proofs, and especially to the Treasurer, under whose experienced eye every sheet in the catalogue has passed. The preparation of copy for a supplementary volume, which will include papers from a large number of periodicals not included in the existing volumes, is now nearing completion.

The Catalogue Committee have held several meetings and discussed some important questions. The proposed subject-index to the existing catalogue has been the chief matter under consideration, and the burning question of the respective merits of an alphabetical and a classified index has been so far settled as to make it possible to commence the work of transcription and translation, nearly 40,000 slips being already finished, so that when the details of the plan agreed upon have been finally settled, as there is good hope they will be in the near future, the preparation of the copy for the printer can be speedily proceeded with. Before, however, any final steps can be taken, it will be necessary that the supplement volume of the catalogue should have issued from the press. The preparations for this volume are in active progress.

A kindred subject, but one of still wider scope, has been discussed by a special committee appointed by the Council at their first meeting in the present session. The question, namely, of a scientific subject-catalogue, which it is proposed to carry out by means of international co-operation. This committee, with the sanction of the Council, have addressed a circular letter to scientific societies and institutions in this country and abroad, offering by way of preliminary suggestions, first, that the catalogue should commence with the next century; secondly, that a central office or bureau should be maintained by international contributions; and third, that this office should be supplied with all the information necessary for the construction of the catalogue. The circular invites the views on this subject of scientific bodies and scientific men, without in any way committing the Society to farther action. A large number of replies to this circular have been received, many of them carefully prepared and able documents. They will be submitted to the new Council of the Royal Society, and will, I am sure, be most valuable in assisting it to judge as to future proceedings.

The principal question which the Library Committee have had before them during the past session is the accumulation of the stock of *Philosophical Transactions* from the beginning of the century to the present time. New racks have been erected in the basement, which have partly relieved the pressure on our space, but the Committee recognise the necessity of some active measures being taken to increase the sale of this accumulated stock. They are of opinion that the sale might be much facilitated if the memoirs composing the volumes published in the past were made separately available to the public, as is done with those that are published at the present time. On the advice of the committee, the Council have empowered the Treasurer to treat with one of the leading booksellers with the view of bringing some such arrangement into effect.

The collection of marble busts belonging to the Society, which is of such personal and historical interest to all our Fellows, has received a most important and valuable accession. The sons of our former President, Mr. William Spottiswoode—Messrs. Hugh and Cyril Spottiswoode—have presented to the Society a marble bust of their father, by Woolner, which will find in our apartments a fitting home among the busts of many of our former Presidents and distinguished Fellows, and will hand down to posterity a striking likeness of one who deserved so well of the Society and whose premature decease we all still deplore.

The House and Soirée Committee have discussed the advisability of increasing the accommodation in the tea room, and have presented a report to the Council upon the subject. The Council, while not disagreeing with this report, considered it wiser, in the present state of finances, to defer the matter for a time.

A third report of the Water Research Committee has been issued during the present year. It gives the results of further experiments by Prof. Marshall Ward on the "Action of Light on Bacillus Anthracis," and on the "Bacteria of the Thames," and the experiments of Prof. Percy Frankland on the "Behaviour of the Typhoid Bacillus and of the *Bacillus Coli Communis* in Potable Water," the whole filling 242 octavo pages.

Unusually large as was the amount of matter published last year, this year the amount is even larger. In the mathematical and physical section of the *Philosophical Transactions*, seventeen papers have been published, eighteen in the biological section. The two sections together contain, in all, 1992 pages of letterpress, and 112 plates; to which must be added eight or ten papers now passing through the press, and probably to be issued before the close of the year. Of the *Proceedings*, ten numbers have been issued, containing 1026 pages. As a result, the finances of the Society are, I regret to say, in not such a satisfactory condition as could be desired. The cost of the publications, which, last year, was far in excess of what it was in previous years, and of what the Society could really afford, has, in the year 1894, amounted to nearly £3260, or about £90 more than it was in 1893. For lithography and engraving alone £1516 have been paid, as against £977 last year. There is, moreover, an accumulation of printed matter now almost in readiness to be issued, the cost of which has still to be defrayed. To meet this extraordinary expenditure it has been necessary to sell out enough of the Society's funded capital to produce £1000, and rigorous retrenchment will be necessary in order to avoid further loss of provision for continued work in future. While the Council feels the importance of all the publications of the Society being as completely illustrated and as fully detailed as the subjects discussed may require, it is evident that some check must be placed on the extent of the publications, and the best manner of effecting this end is occupying the careful attention of the Council.

The establishment of the Faraday-Davy Research Laboratory, in connection with the Royal Institution, is a splendid benefaction which science has gained during the past year, through the untiring and grand generosity of Mr. Ludwig Mond. The Royal Society interests itself in all work contributing towards the object for which it was founded—the increase of natural knowledge; and while gratefully remembering the assistance so generously given to it in the humble but highly valuable work of cataloguing papers which describe the results of scientific investigations already made, it hails with delight this grand foundation of a practical laboratory, of which the purpose is not the teaching of scientific truths already discovered, but the conquering of fresh provinces from the great region of the unknown in nature.

The greatest scientific event of the past year is, to my mind, undoubtedly the discovery of a new constituent of our atmosphere. If anything could add to the interest which we must all feel in this startling discovery, it is the consideration of the way by which it was found. In his presidential address to Section A of the meeting of the British Association at Southampton in 1882, Lord Rayleigh, after calling attention to Prout's law, according to which the atomic weights of the chemical elements stand in simple relationship to that of hydrogen, said:—"Some chemists have reprobated strongly the importation of *à priori* views into the consideration of the question, and maintain that the only numbers worthy of recognition are the immediate results of experiment. Others, more impressed by the argument that the close approximations to simple numbers cannot be merely fortuitous, and more alive to the inevitable imperfections of our measurements, consider that the experimental evidence against the simple numbers is of a very slender character, balanced, if not outweighed, by the *à priori* argument in favour of simplicity. The subject is eminently one for further experiment; and as it is now engaging the attention of chemists, we may look forward to the settlement of the question by the present generation. The time has, perhaps, come when a redetermination of the densities of the principal gases may be desirable—an undertaking for which I have made some preparations." The arduous work thus commenced in 1882, has been continued for twelve years,[1] by Rayleigh, with unremitting perseverance. After

[1] "On the relative Densities of Hydrogen and Oxygen. Preliminary Notice," by Lord Rayleigh, February 2, 1888. "On the Composition of Water," by Lord Rayleigh, February 26, 1889. "On the relative Densities of Hydrogen and Oxygen. II." By Lord Rayleigh, February 5. 1892. "On the Densities of the principal Gases," by Lord Rayleigh, March 23, 1893. "On an Anomaly encountered in Determinations of the Density of Nitrogen Gas," by Lord Rayleigh, April 19, 1894. All published in the *Proceedings* of the Royal Society.

twelve years of it, a first important part of the object, the determination of the atomic weight of oxygen with all possible accuracy was attained by the comparison,[1] of Scott's determination of the ratio of the volumes of hydrogen and oxygen in the constitution of water, with Rayleigh's determination of the ratio of the densities. The result was 15·82, which is almost 1 per cent. (0·87 per cent.) less than the 16, which it would be according to Prout's law. It is very slightly less (¼ per cent.) than Dittmar and Henderson's value obtained by an investigation[2] for which the Graham medal of the Glasgow Philosophical Society was awarded in 1890. Values, not quite so small as these for the atomic weight of oxygen, had been previously found by Cooke and Richards (15·869) and by Leduc (15·876). There can be no doubt whatever now that the true value is more than ½ per cent. smaller than according to Prout's law, and that in all probability it agrees exceedingly closely with the results obtained by Rayleigh and Scott, and by Dittmar and Henderson. The question of Prout's law being thus so far set at rest, Rayleigh, persevering in the main object which he had promised in 1882, "a redetermination of the densities of the principal gases," attacked nitrogen resolutely and, stimulated by most disturbing and unexpected difficulties in the way of obtaining concordant results for the density of this gas as obtained from different sources, discovered that the gas obtained by taking vapour of water, carbonic acid, and oxygen from common air was denser[3] by 1/230 than nitrogen obtained by chemical processes from nitric oxide or from nitrous oxide, or from ammonium nitrite, thereby rendering it probable that atmospheric air is a mixture of nitrogen, and a small proportion of some unknown and heavier gas. Rayleigh and Ramsay, who happily joined in the work at this stage, have since succeeded in isolating the new gas, both by removing nitrogen from common air by Cavendish's old process of passing electric sparks though it, and taking away the nitrous compounds thus produced by alkaline liquor; and by absorption by metallic magnesium. Thus we have a fresh and most interesting verification of a statement which I took occasion to make in my presidential address to the British Association in 1871,[4] "Accurate and minute measurement seems to the non-scientific imagination a less lofty and dignified work than looking for something new. But nearly all the grandest discoveries of science have been but the rewards of accurate measurement and patient long-continued labour in the minute sifting of numerical results." The investigation of the new gas is now being carried on vigorously, and has already led to the wonderful conclusion that the new gas does not combine with any other chemical substance which has hitherto been presented to it. We all wait with impatience for further results of their work; we wish success to it, and we hope that it will give us, before the next anniversary meeting of the Royal Society, much knowledge of the properties, both physical and chemical, of the hitherto unknown and still anonymous fifth constituent of our atmosphere.

Copley Medal.

Dr. Edward Frankland, F.R.S.

The Copley Medal is awarded to Dr. E. Frankland for his eminent services to theoretical and applied chemistry.

At a time when the classification of organic compounds in homologous series was a comparative novelty, when isomerism was still a profound mystery, and the theory of compound radicles introduced by Liebig was still on its trial, Dr. Frankland made his first attempt (in 1848) to isolate the radicle of common alcohol. Though the attempt was in one sense unsuccessful, inasmuch as the free radicle was never obtained, for reasons which we now more fully understand, the research led to important consequences. The discovery of the organo-metallic compounds, and the study of their composition and properties, was followed by a recognition of the fact, first that the capacity for combination possessed by the atoms of the metals was limited (*Phil. Trans.*, 1852), and secondly that variation of "atomicity," as it was then called, usually occurs by an even number of units (*Journ. Chem. Soc.*, 1866), represented by atoms of hydrogen, chlorine, or such compound radicles as methyl, ethyl, and the rest. These discoveries form the basis of the modern doctrine of valency, with all the important consequences that follow, including the idea of the orderly linking of atoms, and hence the theories of structure or constitution now current.

The discovery of zinc ethyl placed in the hands of chemists an important new instrument of research, which Dr. Frankland was himself the first to use in his investigations concerning the synthetical production of acids of the lactic and acrylic series. Further important synthetical work, conducted in concert with Mr. Duppa, led to a method of ascending the series of acids homologous with acetic acid.

Dr. Frankland's researches in pure chemistry are almost rivalled in interest by his discoveries in physical chemistry, especially in relation to the influence of pressure on the rate of combustion, on the light emitted during combustion, and on the cause of luminosity in hydrocarbon flames.

The important work done by Dr. Frankland in the study of water supply and sewage, and illuminating gas, has proved of great practical value, and has rendered his name famous in connection with the application of chemistry to technical purposes.

Rumford Medal.

Professor Dewar.

During more than twenty years past Prof. Dewar has been engaged in researches of great difficulty, in the first instance at very high, and latterly at very low temperatures, his inquiries having extended over an extraordinary wide field, as will be seen by reference to the "Royal Society Catalogue" of scientific papers.

In conjunction with Prof. Liveing, he has communicated to the Royal Society a large number of papers which have added much to our knowledge of spectroscopic phenomena.

During recent years he has made the liquefaction of gases a subject of deepest study, and in the course of this work has displayed not only marvellous manipulative skill and fertility of resource, but also great personal courage, such researches being attended with considerable danger. One of his chief objects has been so to improve and develop the methods of liquefying the more permanent gases that it shall become possible to deal with large quantities of liquid, and to use such liquids as instruments of research in extending our knowledge of the general behaviour of substances at very low temperatures. In this he has already been highly successful. Not only has he succeeded in preparing large quantities of liquid oxygen, but he has been able by the device of vacuum-jacketed vessels to store this liquid under atmospheric pressure during long periods, and thus to use it as a cooling agent. Very valuable outcome of these labours has been the series of determinations, made by him in conjunction with Dr. Fleming, of the electrical conductivity of metals at exceedingly low temperatures, which have furnished results of a most unexpected character, and of extraordinary interest and importance. Prof. Dewar's experiment showing the great magnetic susceptibility of liquid oxygen is exceedingly important and interesting. His recent observations on phosphorescence, and on photography,[1] and on ozone[2] at very low temperatures, have given surprising results of a highly instructive and interesting character. It is difficult to exaggerate the importance of extending these researches, which certainly deserve all possible encouragement and support. The award of the Rumford Medal to Prof. Dewar is made in recognition of the services which he has rendered to science by the work which he has already done and the provision he has been successful in making for future work, in the investigation of properties of matter at lowest temperatures.

Royal Medal.

Prof. J. J. Thomson, F.R.S.

Prof. J. J. Thomson has distinguished himself in both mathematical and experimental fields of work. His first essay on vortex rings showed power of grappling with difficult problems, and added to our knowledge concerning the encounter of rings which came within a moderate distance of one another so as to deflect each others' paths.

His theoretical work in the borderland of chemistry and physics has been very interesting and suggestive. His experimental work has likewise been mainly on the borders of chemistry and physics. He has observed the large conductivity

of many gases and vapours, and proved the non-conducting power of several others, founding on the conducting power of iodine vapour important speculations as to its probable chemical constitution.

He has also measured the specific resistance of various electrolytes, under extremely rapid electric oscillations, by an ingenious and valuable method, based on the partial opacity of semi-conducting matter to electromagnetic waves. Recently he has worked at the discharge of electricity through rarefied gases, getting induced currents in closed circuits in sealed bulbs without electrodes, and, in especial, measuring to a first approximation the absolute velocity of the positive discharge through a long vacuum tube, proving that it was comparable with, though decidedly less than, the velocity of light. He also gave an ingenious theory of the striæ—a theory which he has since endeavoured, with some success, to extend to a large number of electrical phenomena, the whole of electric conduction and induction being regarded by him from the chemical side as a modified or incipient electrolysis, or as concerned with electrolytic chains of molecules or "Faraday tubes."

Some of his recent mathematical work on the theory of electric oscillations in spheres and cylinders, and in dumb-bell oscillators of the kind used by Hertz, with reference to not only their oscillation-frequency but also their damping efficiency, has been of much service to experimental workers in those branches of physics. And, in general, the effective manner in which he attacks any electrical problem presenting itself, as evidenced by his book on "Recent Researches in Electricity and Magnetism," wherein he worthily carries on into a third volume the great treatise begun by Clerk Maxwell, is evidence of consummate ability combined with remarkable energy and power of work.

ROYAL MEDAL.

Prof. Victor Horsley, F.R.S.

A Royal Medal is awarded to Prof. Victor Horsley, F.R.S., for his laborious and fruitful researches in physiology and pathology, and particularly for those relating to the functions of the nervous system and of the thyroid gland. His inquiries relating to the former subject have been pursued for more than ten years, and have been communicated to the Royal Society in a succession of papers, the most important of which have been published in the *Philosophical Transactions*. The first of the series of researches (*Phil. Trans.*, 1888), which was conducted in co-operation with Prof. Schäfer, and concerned the relation of a part of the cerebral cortex (the limbic lobe) to sensation, afforded a new confirmation and extension of the doctrine of the localisation of cerebral function now generally accepted. While this work was in progress, Prof. Horsley engaged with Dr. Beevor in a long and laborious series of experiments for the purpose of determining with the utmost attainable accuracy the nature of the muscular responses which are evoked by stimulating the convolutions in the quadrumana. The results of these researches were communicated in four papers, of which the first three relate to the "cortical representations" of the movement of the limbs, and of those of the tongue and face (*Phil Trans.*, 1887–1890); the fourth on the channels (in the internal capsule) by which the cortex exercises its influence on the rest of the nervous system (*Phil. Trans.*, 1890).

These experiments not only served to bring to light a number of new facts, and to elucidate their physiological relations in a very remarkable way, but had a special interest in their bearing on the physiology and pathology of the brain in man. Their importance in this respect is enhanced by the circumstance that in the course of the inquiry the opportunity offered itself of comparing the brain of the monkey with that of the orang (*Phil. Trans.*, 1890), a brain which so closely approaches that of man in its structure that the knowledge acquired by these researches may now be confidently used as a guide in the diagnosis and treatment of cerebral disease. Prof. Horsley has himself shown—and this is not the least of the merits which it is desired to recognise in the bestowal of the Royal Medal—in how many instances the knowledge which is acquired by patient and skilful work in the laboratory may be made available for the saving of life, or the alleviation of human suffering.

In connection with this leading series of researches, two others relating to the physiology of the central nervous system must be referred to. In one of these (*Phil. Trans.*, 1890), Prof. Horsley (in co-operation with Dr. Semon) established the existence, not only of a co-ordinating centre in the bulb, but of a cortical area in physiological relation with the respiratory and phonatory movements of the larynx; in the other, in conjunction with Prof. Gotch, he investigated the electrical changes in the spinal cord which are associated with excitation of the cortex and internal capsule, and showed how the observation of these facts can be made available for tracing channels of conduction in the cord.

As regards the thyroid gland, Prof. Horsley's inquiries relating to functions of that organ were like those relating to the nervous system, begun ten years ago, though the results were not communicated to the Royal Society until three years later. Their purpose was to ascertain the nature of the very marked influence which the thyroid was known to exercise on the nutritive functions of the organism, and to show that this influence is constant and definite. In this field, Prof. Horsley has not only the merit of having been one of the earliest workers, but of having at this early period arrived at results which the numerous investigations of subsequent writers have in all essential particulars confirmed.

DAVY MEDAL.

Prof. Peter Theodor Cleve.

The Davy Medal is awarded to Peter Theodor Cleve, Professor of Chemistry in the University of Upsala, for his services to chemical science during the last thirty years, and in particular for his long-continued and valuable researches on the chemistry of the rare earths.

This field of inquiry is pre-eminently Scandinavian. By the manner in which he has cultivated it, Prof. Cleve has shown himself a worthy successor of such forerunners as Gadolin, Berzelius, and Mosander, and by sound and patient investigation he has faithfully upheld the traditions inseparably associated with these names. All chemists are agreed that no department of their science demands greater insight or more analytical skill than this particular section. Many of the minerals which furnish the starting-point for investigation are extremely rare, and the amounts of the several earths which they contain are frequently very small. Moreover, the substances themselves are most difficult of isolation, and their characters are so nearly allied that the greatest care and judgment are required in order to determine their individuality.

A remarkable example of Prof. Cleve's power in overcoming these difficulties is seen in his masterly inquiry into the affinities and relations of the element scandium, discovered by Nilson. This, one of the rarest of the metals, is found only in gadolinite to the extent of 0·003 per cent., and in yttrotitanite to the extent of about 0·005 per cent. The whole amount of the material, as oxide, at Cleve's disposal was only about 1 gram, but with this small quantity he determined the atomic weight of the element, and ascertained the characters of its salts with such precision as to leave no doubt of the identity of scandium with the element *Ekabor*, the existence of which was predicted by Mendeléef, in the memorable paper in which he first enunciated the Law of Periodicity. Cleve's research, indeed, constitutes one of the most brilliant proofs of the soundness of the great generalisation which science owes to the Russian chemist.

A not less remarkable instance of Cleve's skill as a worker is seen in his research on samarium and its compounds, which he communicated as one of its Honorary Foreign Fellows to the Chemical Society of London. The existence of samarium was inferred independently by Delafontaine and Lecoq de Boisbaudran, but we owe to Cleve the first comprehensive investigation of its characters and chemical relations. From the nature of its compounds, a large number of which were first prepared and quantitatively analysed by Cleve, and from the value of its atomic weight, which was first definitely established by him, it would appear that samarium most probably fills a gap in the eighth group of Mendeléef's system.

We are further indebted to Cleve for a series of determinations of the atomic weights of the rare substances yttrium, lanthanum, and didymium; these are generally accepted as among the best authenticated values for these particular bodies.

No record of Cleve's scientific activity would be complete without some reference to his investigations in the domain of organic chemistry, and more particularly to his studies, extending over twenty years, of naphthalene derivatives. By these researches, made partly independently, and partly in conjunction with his pupils, among whom may be named Atterberg, Widman, Forsling, and Hellström, Cleve has gradually brought order out of confusion, and has supplied most valuable experimental evidence of the constitution of naphthalene, and of the course of substitution of naphthalene derivatives. Within recent years a score of workers have occupied themselves with the same field of research, and no greater proof of Cleve's accuracy and care as an investigator could be furnished than the manner in which his naphthalene work—confessedly one of the most intricate and complicated sections of the chemistry of aromatic compounds—has stood the ordeal of revision.

Darwin Medal.

Right Hon. T. H. Huxley, F.R.S.

The Darwin Medal is awarded to Thomas Henry Huxley.

Of Mr. Huxley's general labours in biological and geological science I need say nothing here. They are known of all men, and the Society showed its appreciation of their worth when it awarded to him the Copley Medal in 1888. The present medal is a token of the value put by the Society on the part of his scientific activity bearing more directly on the biological ideas with which the name of Charles Darwin will always be associated.

All the world now knows in part, no one perhaps will ever know in full, how, in the working out of his great idea, Darwin was encouraged, helped, and guided by constant communion with three close and faithful friends, Charles Lyell, the younger Joseph Dalton Hooker, and the still younger Thomas Henry Huxley. Each representing more or less different branches of science, each bringing to bear on the problems in hand more or less different mental characters, all three bore share, and were proud to bear share, in aiding the birth of the "Origin of Species." Charles Lyell has long been removed from amongst our midst. Two years ago it was my pleasing duty to place the Darwin Medal in the hands of Joseph Dalton Hooker; that pleasing duty is renewed to-day in now giving it to the last of the three "who kept the bridge."

To the world at large, perhaps, Mr. Huxley's share in moulding the thesis of "Natural Selection" is less well known than is his bold unwearied exposition and defence of it after it had been made public. And, indeed, a speculative trifler, revelling in problems of the "might have been," would find a congenial theme in the inquiry how soon what we now call "Darwinism" would have met with the acceptance with which it has met, and gained the power which it has gained, had it not been for the brilliant advocacy with which in its early days it was expounded to all classes of men.

That advocacy had one striking mark; while it made or strove to make clear how deep the new view went down and how far it reached, it never shrank from striving to make equally clear the limits beyond which it could not go. In these latter days there is fear lest the view, once new but now familiar, may, through being stretched farther than it will bear, seem to lose some of its real worth. We may well be glad that the advocates of the "Origin of Species by Natural Selection," who once bore down its foes, is still among us ready, if needs be, to "save it from its friends."

The Society next proceeded to elect the officers and Council for the ensuing year. We gave the list of those recommended for election in our issue of November 8.

In the evening the Fellows and their friends dined together at the Whitehall Rooms of the Hôtel Métropole.

After the usual toasts, the President proposed that of "The Medallists," coupling with it the names of Prof. Cleve and Mr. Huxley. The toast was most cordially drunk. The *Times* reports the responses as follows:—

Prof. Cleve, in responding, quoted the noble words of Davy—"Science, like that nature to which it is bound, is neither limited by time nor by space; it belongs to the world, and is of no country and of no age." In the same sense the Royal Society continued to award its medals to men of science, without regard to their nationality. It was a great and elevating thought that there existed a spot in the world where members of all nations met each other as friends, assisting each other in their work for the advancement of science, and therefore for the good of humanity and the prosperity of mankind. It was the first time that the Davy medal had found its way to Sweden, but it was not the first time that other medals of the Royal Society had been voted to Professors of the Vniversity to which he was attached. The Rumford medal had been given not less than three times to his colleagues, and when he offered to the Royal Society his respectful thanks he was happy to include also those of the University of Upsala.

Mr. Huxley said—I am extremely grateful for the respite which has been afforded me by the distinguished foreigner to whom you have just been listening with so much pleasure, because I am loaded with five distinct and separate parcels of gratitude. That is a substance of which I believe the specific gravity has never yet been accurately determined. I am told that in some parts of the world, and especially in the political world, it is lighter than hydrogen; but in the scientific world, and when the object of it is the approbation of a body like the Royal Society, I am disposed to think that we may rank it rather with platinum, so largely does it affect the destinies of those who are fortunate enough to receive it. In respect of four of these parcels I am simply a representative, and perhaps I ought to content myself with acting purely as a representative of those who I wish had been called upon to express their gratitude for themselves. But perhaps I may venture to add that in some cases I have a little personal word to say for myself, as, for example, in that of the Copley medal, which you have adjudged one of my oldest friends and many years a colleague, so that I have a strong and warm interest in the fact that his great services to the science of chemistry have been recognised. And, again, I think that there is another friend in whom I may claim a personal interest—I mean my friend Prof. Dewar—for the remarkable character of his discoveries allows a person who indulges so little in flights of imagination as myself to think of the time when, instead of the excellent liquid with which we have been supplied here, we may have at these dinners of the Royal Society liquid oxygen *bien frappé*, and then, gentlemen, with that stimulus there is no saying to what length the eloquence of persons who address you may go. And then, again, in one of the youngest of those whom you have honoured with your approbation to-day, and whose work lies within the province in which I am still capable if not of knowledge at least of appreciation—I mean Prof. Victor Horsley—I may say that it is pleasant to me to see him here like a Ulysses who has escaped from the toils of the Circes of anti-vivisection. But the most difficult task that remains is that which concerns myself. It is forty-three years ago this day since the Royal Society did me the honour to award me a Royal medal, and thereby determined my career. But, having long retired into the position of a veteran, I confess I was extremely astonished—I honestly also say that I was extremely pleased—to receive the announcement that you had been good enough to award to me the Darwin medal. But you know the Royal Society, like all things in this world, is subject to criticism. I confess that with the ingrained instincts of an old official that which arose in my mind after the reception of the information that I had been thus distinguished was to start an inquiry which I suppose suggests itself to every old official—How can my government be justified? In reflecting upon what had been my own share in what are now very largely ancient transactions it was perfectly obvious to me that I had no such claims as those of Mr. Wallace. It was also perfectly clear to me that I had no such claims as those of my life-long friend Sir Joseph Hooker, who for twenty-five years placed all his great sources of knowledge, his sagacity, his industry, at the disposition of his friend Darwin. And really, I began to despair of what possible answer could be given to the critics whom the Royal Society, meeting as it does on November 30, has lately been very apt to hear about on December 1. Naturally there occurred to my mind that famous and comfortable line, which I suppose has helped so many people under like circumstances, "They also serve who only stand and wait." I am bound to confess that the standing and waiting to which I refer, has been, so far as I am concerned, of a somewhat peculiar character. I can only explain it, if you will permit me to narrate a story which came to me in my old nautical days, and which, I believe, has just as much foundation as a good deal of other information which I derived at the same period from the same source. There was a merchant ship in which a member of the Society of Friends had taken passage. That ship was attacked by a pirate, and the captain thereupon put into the hands of the member of the Society of Friends a pike, and desired him to take part in the subsequent action, to which, as you may imagine, the reply was that he would do nothing of the kind; but he said that he had no objection to stand and wait at the gangway. He did stand and wait with the pike in his hand, and when the pirates mounted and showed themselves coming on board, he thrust his pike (with the sharp end forward) into the persons who were mounting, and he said, "Friend, keep on board thine own ship." It is in that sense that I venture to interpret the principle of standing and waiting to which I have referred. I was convinced as firmly as I have ever been convinced of anything in my life that the "Origin of Species" was a ship laden with a cargo of great value, and which, if she were permitted to pursue her course, would reach a veritable scientific Golconda, and I thought it my duty, however naturally averse I might be to fighting, to bid those who would disturb her beneficent operations to keep on board their own ship. If it has pleased the Royal Society to recognise such poor services as I may have rendered in that capacity I am very glad, because I am as much convinced now as I was thirty-four years ago that the theory propounded by Mr. Darwin, I mean that which he propounded —not that which has been reported to be his by too many ill-instructed, both friends and foes—has never yet been shown to be inconsistent with any positive observations, and if I may use a phrase which I know has been objected to and which I use in a totally different sense from that in which it was first proposed by its first propounder, I do believe that on all grounds of pure science it "holds the field," as the only hypothesis at present before us which has a sound scientific foundation. It is quite possible that you will apply to me the remark that has often been applied to persons in such a position as mine, that we are apt to exaggerate the importance of that to which our lives have been more or less devoted. But I am sincerely of opinion that the views which were propounded by Mr. Darwin thirty-four years ago will be understood hereafter to mark an epoch in the intellectual history of the human race. They will modify the whole system of our thoughts and opinions, and shape our most intimate convictions. I do not know, I do not think anybody knows, whether the particular views which Darwin held will be fortified by the experience of the ages which come after us. But of this thing I am perfectly certain, that the present state of things has resulted from the feeling of the smaller men who have followed him that they are incompetent to bend the bow of Ulysses, and in consequence many of them are preferring to employ the air-gun of mere speculation. Those who wish to attain to some clear and definite solution of the problems which Mr. Darwin was the first person to set before us in later times, must base themselves upon the facts which are stated in his great work, and, still more, must pursue their inquiries by the methods of which he was so brilliant an exemplar throughout the whole of his life. You must have his sagacity, his untiring search after the knowledge of fact, his readiness always to give up a preconceived opinion to that which was demonstrably true, before you can hope to carry his doctrines to their ultimate issue; and whether the particular form in which he has put them before us may be such as is finally destined to survive or not is more, I venture to think, than anybody is capable at this present moment of saying. But this one thing is perfectly certain—that it is only by pursuing his methods, by that wonderful single-mindedness, devotion to truth, readiness to sacrifice all things for the advance of definite knowledge, that we can hope to come any nearer than we are at present to the truths which he struggled to attain.

THE BATTLE OF THE FORESTS.[1]

II.

IN the sand-hills which traverse Nebraska from east to west there are now found in eastern counties the sand-drowned trunks of the western bull pine, and the same pine belonging to the Pacific flora is found associated with the black walnut of the eastern region along the Niobrara River.

We may, however, divide the North American forest, according to its botanical features, into two great forest regions, namely, the Atlantic, which is in the main characterised by broad-leaved trees, and the Pacific, which is made up almost wholly of coniferous species.

In the Atlantic forest we can again discern several floral subdivisions, each of which shows special characteristics. The southernmost coast and keys of Florida, although several degrees north of the geographical limit of the tropics, present a truly tropical forest, rich in species of the West Indian flora, which here finds its most northern extension. There is no good reason for calling this outpost semi-tropical, as is done on Sargent's map. With the mahogany, the mastic, the royal palm, the mangrove, the sea grape, and some sixty more West Indian species represented, it is tropical in all but its geographic position. That the northern flora joins the tropic forest here, and thus brings together on this insignificant spot some hundred species, nearly one quarter of all the species found in the Atlantic forest, does not detract from its tropical character.

On the other hand, the forest north of this region may be called sub-tropical, for here the live and water oak, the magnolia, the bay tree and holly, and many other broad-leaved trees are mixed with the sabal and dwarf palmatto. As they retain their green foliage throughout the winter, this region is truly semi-tropical in character, and under the influence of the Gulf Stream, extends in a narrow belt some twenty or twenty-five miles in width along the coast as far north as North Carolina.

While this ever-green, broad-leaved forest is more or less confined to the rich hammocks and moister situations, the poor sandy soils of this as well as of the more northern region are occupied by pines; and as those, especially the long leaf pine, are celebrated all over the world, and give the great mercantile significance to these forests, this region may well be called the great southern pine belt. North of the evergreen subtropic forest stretches the vast deciduous leaved forest of the Atlantic, nowhere equalled in the temperate regions of the world in extent and perfection of form, and hardly in the number of species. This designation applies to the entire area up to the northern forest belt, for the region segregated on the census map as the northern pine belt is still in the main the dominion of the deciduous-leaved forest trees. On certain areas pines and spruces are intermixed, and on certain soils, especially gravelly drifts and dry sand plains, as on the pine barrens of Northern Michigan, they congregate even to the exclusion of other species. Instead, we can divide this deciduous-leaved forest by a line running somewhere below the fortieth degree of latitude, where with the northern limits of the southern magnolias and other species we may locate in general the northern limit of the southern forest flora. Northward from here, in what may be called the "middle Atlantic forest," the deciduous species rapidly decrease, and the coniferous growth predominates, until we arrive at the broad belt of the northern forest, which, crossing from the Atlantic to the Pacific, and composed of only eight hardy species, takes its stand against the frigid breath and icy hands of Boreas.

Abounding in streams, lakes, and swampy areas, the low divides of this region are occupied by an open stunted forest of black and white spruce, while the bottoms are held by the balsam fir, larch or tamarack, poplar, dwarf birch and willow. The white spruce, paper or canoe birch, balsam poplar and aspen stretch their lines from the Atlantic to the Pacific over the whole continent.

On the Pacific side the subdivisions are rather ranked from west to east. While the northern forest battles against the cold blasts from icy fields, the front of the Pacific interior forest is wrestling with the dry atmosphere of the plains and interior basin. Here, on the driest parts, where the sage brush finds its home, the ponderous bull pine is the foremost fighter, and where even this hardy tree cannot succeed in the interior basin several species of cedar hold the fort, in company with the nut pine, covering with an open growth the mesas and lower mountain slopes. Small and stunted, although of immense age, these valiant outposts show the marks of severe struggles for existence.

On the higher, and therefore moister and cooler elevations, and in the narrow canyons, where evaporation is diminished and the soil is fresher, the sombre Douglas, Engelmann, and blue spruce, and the silver-foliaged white fir, join the pines or take their place.

With few exceptions, the same species, only of better development, are found in the second parallel, which occupies the western slopes of the Sierra Nevada. Additional forces here strengthen the ranks, the great sugar pine, two noble firs, a mighty larch, hemlocks and cedars vie with their leaders, the big sequoias, in showing of what metal they are made. The third parallel, occupied by the forest of the Coast Range, the most wonderfully developed, although far from being the most varied of this continent, is commanded by the redwood, with the tide-land spruce, hemlock, and gigantic arborvitæ joining the ranks.

[1] A lecture delivered by Prof. B. E. Fernow, Chief of the Forestry Department of Agriculture, U.S.A., during the Brooklyn meeting of the American Association for the Advancement of Science. (Continued from page 119.)

Broad-leaved trees are not absent, but so little developed in comparison with the mighty conifers that they play no conspicuous part except along the river bottoms, where the maple, cottonwood, ash, and alder thrive, and in the narrow interior valleys, where an open growth of oak is found. Towards the south and on the lower levels these broad-leaved trees again become evergreen, as on the Atlantic side, but of different tribes, and form a sub-tropic flora.

Along the coast we find several species of true cypress, including the well-known, although rare, Monterey cypress, which clings to the gigantic rocks, and braves the briny ocean winds, and with its branches twisted landward. Finally, flanking the battle order of the Pacific forest, we find another section of the army, composed of the northern extension of the Mexican flora, mingled with which are species from the Pacific forest on the west, and from the Atlantic on the east.

The mesquite and some acacias, the tree yuccas and the giant or tree cactus are perhaps the most characteristic and remarkable species of the deserts of this region, while the high mountains support dense forests of firs and pines.

So far we have considered the forest only from the geographical and botanical point of view, and have watched the history of its struggle for existence against the elements and against the lower vegetation and other forces of nature. A new chapter of its life history, which we shall have time only to scan very briefly, began when man came upon the scene, and the economic point of view had to be considered.

For ages man has taken sides against the forest. Not only has he contested for the occupancy of the soil, in order to cultivate his crops or to make the meadow for his cattle—a most legitimate and justifiable proceeding—and not only has he utilised the vast stores of wood accumulated through centuries, for the ten thousand uses to which this material can be applied, and in the application of which he exhibits his superior intelligence, but he has also shown a woeful lack of intelligence in the wilful or careless destruction of the forest without justifiable cause, and by just so much curtailing the bountiful stores provided by nature for him and his progeny. Not only has he, like a spendthrift, wasted his stores of useful material, but more—he has wasted the work of nature through thousands of years by the foolish destruction of the forest cover, wresting from it the toilsomely achieved victory over the soil. He has destroyed the grasses and even all vestige of vegetation, and has handed over the naked soil to the action of wind and water. As the fertility and agriculture of the plain is dependent upon the regular and equable flow of water from the mountains, such as a forest cover alone can secure, he has by barring the slopes accomplished in many localities utter ruin to himself, and turned them back into inhospitable deserts as they were first before the struggle of the forest had made them inhabitable.

One would hardly believe that certain mountains in France had ever seen a luxuriant forest growth, and could during historic times have been so utterly despoiled of their vegetal cover. Yet axe, fire, and cattle have been most successful, and the consequences have been felt not only in the mountains, but in the valleys below. The waters in torrents have brought down the soil and débris, covering out of sight the fertile fields of thousands of toiling farmers. They themselves have brought this ruin upon them on account of their ignorance of the relation of forest cover to their occupation. Now, with infinite hard work and expenditure of energy and money, the slow work of restoring the forest to its possession has begun. The first work is to take care of the rain-waters, and by artificial breaks turn them from rushing torrents over the bare surface into a succession of gentle runs and falls by fascine and stone works. This work must be begun at the very top of the mountains, at the very source of the evil, where the water receives its first momentum in the descent to the valley. The fascines or wattles, laid across each rivulet at more or less frequent distances from each other, and fastened down by heavy stones, are made of live willows or other readily sprouting species, which in course of time strike root and become living barriers. The pockets behind these breastworks gradually fill up, and the contour of the mountain-side is changed from an even and rapid descent into a series of steps with gentle fall, over which the formerly rushing waters, gradually and without turbulence, find their way to the valley below. Where the incline is too steep, and higher breastworks are necessary, they are made of masonry, sometimes at great expense. At the base of these overflow dams an opening is left for the water to drain through, even after the depression behind the rampart has filled up with débris, and soil has washed down from above. Then, when in this way the soil has come to rest, forest planting begins, and gradually the torrent is "drowned in vegetation." Sometimes, where on a steep mountain-side the naked rock alone has been left, it becomes necessary to carry in baskets the soil to the trenches hewn in the rock, where the little seedlings may take their first hold, until they are strong enough to fight their own battle and make their own soil, gradully restoring the beneficent conditions which nature had provided before the arrival of man and his senseless, improvident, self-destructive greed. By the irrational destruction of the forest, first for the supply of timber, then through the careless use of fire, by the clearing for unsuitable farm use, by excessive grazing of sheep and goat, the mountain-sides themselves are not only devastated and made useless, but fertile farms for two hundred miles from the source of the evil are ruined by the deposits of débris, and the population pauperised and driven from their homes. Many millions of dollars have been and many more will have to be spent before these regions become habitable again.

That we are working in this country towards the same conditions is too well known to need rehearsal. Go to the shores of Lake Michigan, or visit the coast of New England, New Jersey, Pennsylvania, down to the Gulf, and you can see the destructive action of the shifting sands set loose by improvident removal of the plant cover. Go to the Adirondacks, the highlands of Mississippi, or the eastern slopes of the Rocky Mountains, and aspects similar to those derived from France will meet your view.

What the farmer has brought upon himself here by excessive clearing, the lumberer, prospector, miner, or hunter prepares in the farthest West hy reckless and purposeless use of fire. Burnt mountain-sides, where no living thing can subsist in comfort, cover not acres but hundreds of square miles in the western country. While the first fire only deadens the trees or undermines their constitution, the second or third fire usually is sufficient to kill what remain alive, and even to clean up the fallen timber. That these bald spots are not more frequent than they are, is only due to the short period of our endeavours in disturbing the balance of nature.

But as our nation prides itself on the rapidity of its development, exercising to the utmost our constructive energies, so do we excel in destructive and wasteful energies and tendencies, and we shall come to grief with our resources much sooner than some of our happy-go-lucky friends would like to make us believe. While these exhibitions of American vandalism are beyond the proprieties of legitimate warfare, there is not much more propriety or intelligence visible in the manner in which we levy tribute from the forest for our legitimate needs. Forests grow to be used, but there is a great difference between intelligent and unintelligent use. Improvidence and ignorance characterise the present methods of using the forest growth. The value of it is not even known. Of the 425 or more species which are represented in the forests, not more than forty or fifty at the most are found in the markets. Although, to be sure, many of the species are of but little or no economic value, the number of the truly useful trees is probably twice or three times as great as that actually used. Ignorance as to the true value of them keeps many from little more than simply a strictly local use, or from their most fit employment. The story of the black walnut used for fence rails or firewood is well known. Six years ago the red gum or liquidambar, now a fashionable finishing material, was despised. Ten years ago large hemlock trees were mouldering in the woods after the bark had been taken for tanning purposes because the value of the wood was unknown. Cypress and Douglas spruce cannot yet overcome the prejudice of the market. On the other hand, cottonwood and tulip poplar, not long ago among the despised or only locally used, can hardly now be furnished in sufficient quantities, and the long leaf pine, which had been bled for turpentine, was considered an inferior material, which, as has lately been shown, is nothing but an unwarranted prejudice.

In a vague empirical way the choice of the useful has been attempted, and only lately have we begun to systematically study our forest resources, to determine the qualities and adaptabilities of our timbers, and to find out the conditions under which they produce not only the largest amount but the best quality of timber.

Yet in another direction do the forest users act unintelligently.

As we have seen, most of our forest trees are of a social character. With few exceptions, they keep company with other kinds than their own; they appear in mixed forests. Hence, where certain species, as the pines and spruces, become gregarious, and form unmixed, pure forests, the axe of the lumberer does not as a rule level the entire forest, but he selects the kinds which he wishes to use—he culls the forest. At first sight this would appear rather an advantage for the existence of the forest. So it is from a botanic, geographic, or landscape point of view, yet from an economic point it is exactly the reverse—it is disastrous.

In the well-managed forests of Germany the undeserving species are exterminated, and the most useful fostered, just as the agriculturist exterminates the weeds and cultivates the crop. Not only is the forest there confined to those soils and locations which cannot be used to better advantage, or which require a forest cover in order to protect the soil against detrimental displacement, but it is so managed as to become a more and more valuable resource, a crop of increasing importance, under the management of skilled foresters, of whom, in a late debate on the floor of the Landtag of Prussia, it was said that "While most other productive business has declined, the forest administration has steadily improved and yielded increasing revenues."

The battle of the forest in this country is now fought by man, the unintelligent and greedy carrying on a war of extermination, without the knowledge that victory may lead eventually to their own destitution; the intelligent and provident trying to defend the forest cover, and endeavouring to prevent its removal from such lands as cannot serve a better purpose, and to restrict the use of the balance to such rational harvest of its material, without injurious effects on soil and water conditions, as will insure an ever reproducing crop and a permanent national resource.

While man may study the geography of the earth as it exists, here is about the only opportunity for him to make geography, to shape the surface conditions of the earth, and even to some extent influence its climatic conditions.

The lecturer then referred to the Adirondacks in particular, showing views of forest destruction by fire, water storage, and lumbering, and claiming that they need especially conservative treatment, because the soil itself there is made by the forest, the duff covering the native rock formed at the rate of one foot in 300 to 500 years by the decay of foliage and litter, and hence its loss by washing of the rains is practically irremediable.

He showed the paramount interest which the State has in maintaining favourable forest conditions, and claimed that the private owners, being naturally interested mostly in the timber only, and not caring for the future generations or distant and indirect benefits to others, could not be expected to manage conservatively.

Let it not be overlooked, that the State is not only the representative of communal interests as against individual interests, but also of future interest as against the present; the private interest is not sufficient to protect this class of lands; that State ownership or, what is more objectionable and less effective, State supervision of private forest lands is indispensable in those regions where the forest subserves other functions than that of mere material supply.

Grant for once that the community is interested in the preservation of the forest cover and its rational use with proper regard to the maintenance of permanently beneficial conditions, that the community would suffer from a destructive policy in those watersheds, and you must come to the logical conclusion that the community alone can be expected to guard its interests, that the community, the State, must own and manage these woods.

This does not mean that the same should be kept in virgin condition and unused, that the timber should be left to rot, and the productive capacity of nature's forces be allowed to go to waste, but that a conservative management be instituted, keeping in view both the indirect and the direct benefits of the forest cover, utilising the crop without detriment to the forest conditions.

This, to be sure, is not done by such rules of thumb as a restriction to cutting trees of given diameter, nor can the legislator prescribe to the forest how to grow. He cannot be expected to legislate how many trees to cut, how many to leave, or to lay down rules of technical forest management, any more than he would attempt to prescribe the size of the pillars supporting the roof of the Capitol, or to legislate on the proportions of an arch. It requires the knowledge, the experience, the skill of a professional, technically educated engineer, just as an effective management of the forest requires the knowledge, the experience, the skill of professional foresters, and may not be left to the ignorance and carelessness of the wood-chopper.

May the wisdom of the people of New York, of their legislators and executive officers, be equal to the difficulties of solving the problem as a business proposition, and settling it in a common-sense, business-like manner. May their intelligence and business capacity at least equal that of other States and nations, and forestall the disastrous consequences that follow unavoidably from neutrality or improper partisanship in this battle of the forest.

THE RELATION OF ENERGY OF COMBINATION TO ELECTRICAL ENERGY.

THE problem of directly converting the stored-up energy of coal into available electrical energy is one of great importance; and as a first attempt to perform this operation, the experiments made by Dr. W. Borchers, of Duisburg, and which he described before the first annual meeting of the Deutsche Elektrochemische Gesellschaft, possess great interest. The author in the first place produced an electric current by the "combustion" of carbonic oxide gas. The original form of the apparatus used consisted of a glass vessel divided into three compartments by two glass plates which nearly reached to the bottom of the vessel. In the two exterior compartments copper tubes were placed, which served for the introduction of the carbonic oxide, while the middle compartment contained a bell-shaped mass of carbon. This carbon bell constituted one plate of the cell, and the oxygen was introduced by means of a tube within this bell. As electrolyte the author uses an ammoniacal or acid solution of cuprous chloride; this liquid readily absorbs both oxygen and carbonic oxide, and is therefore particularly well suited to form the electrolyte in a gas battery in which these gases are used. Coal gas which contains 5 per cent. of carbonic oxide was, after the first experiments, used in place of pure carbonic oxide. The copper tubes were weighed before and after each experiment, and no decrease in their weight was ever found. With such a cell working through an external resistance of 0·1 ohm a current of 0·5 ampere was obtained, while with an external resistance of 50 ohms the difference of potential between the terminals was 0·4 volt.

With a cell in which the outer compartments were filled with copper turnings, in order to increase the absorption of carbonic oxide by exposing a greater surface, and by using coal gas in place of pure carbonic oxide, a maximum current of 0·64 ampere was obtained, and by increasing the external resistance a maximum difference of potential of 0·56 volt was maintained. The E.M.F. obtained by calculation from the heat developed in the combination of CO and O is 1·47 volts, so that in the above experiment 27 per cent. of the energy of combination of the fuel is converted into electrical energy. Since a solution of cuprous chloride dissolves hydrocarbons, powdered coal was tried in place of carbonic oxide, when a maximum current of 0·4 ampere and a maximum E.M.F. of 0·3 volt were obtained. The above E.M.F. (0·3) corresponds to about 15 per cent. of the energy corresponding to the oxidation of carbon. In the case of the coal-dust, even when the liquid was kept in motion, there was always a considerable falling off in the current, while the pollution of the electrolyte by the coal would quite prevent its use. With the gases, however, there is no falling off of the E.M.F., and this pollution of the electrolyte does not occur.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Dr. R. D. Roberts has been appointed chief secretary for the University Extension scheme, in the room of Mr. A. Berry, who retires at the beginning of the Lent Term 1895.

The General Board of Studies report in favour of steps being taken to establish a closer connection between Addenbrooke's Hospital and the University teachers in the departments of medicine, surgery, and therapeutics.

The Syndics for State Medicine report that in the past year fifty-six candidates presented themselves for examination in this subject; of these thirty-two received the University's diploma in Public Health.

Mr. H. Yule Oldham, University Lecturer in Geography, has been admitted by incorporation to the degree of M.A.

The *University Reporter* of December 3 contains a full report of the speeches delivered at a meeting in King's College for the purpose of promoting the foundation of a memorial library of Oriental literature in honour of the late Prof. Robertson Smith, editor of the *Encyclopædia Britannica*.

SCIENTIFIC SERIAL.

American Meteorological Journal, November.—Cyclonic precipitation in New England, by Prof. W. Upton. A list of cyclones was made out, including nearly all in which the precipitation had been general over New England, and the amounts and distribution noted on maps, with regard to the track of the minimum pressure. The velocity with which the storms passed ranged from fifteen to sixty miles per hour. The tables show that the heaviest rainfall is rarely found along the central path of the storm. Of the cyclones which came from the west *across* New England, only ten out of sixty-nine had their heaviest precipitation on or near the storm-path, while forty-five had the maximum area on the right of the storm-track; similarly, out of eighty-four cyclones which moved from the west *near* New England, seventy-three had their maximum precipitation south of the storm-track. Further comments are reserved until the results of a study of the storms coming from the south are given. —The barometer at sea, by T. S. O'Leary. This paper deals with observations made chiefly by captains of American vessels. The author considers that a great step forward was made when the number of observations was reduced from twelve to one daily, the result being that the number of observers has increased nearly eight-fold. Another valuable feature is that the leaves of the log-books are forwarded to the central office as soon as opportunities are offered, so that the captains can see their observations made use of without delay. A simple plan for obtaining comparisons of the barometers has been adopted with very satisfactory results. The observers when in port record readings at certain hours, and forward them on post-cards to the central office; a copy of the "corrections" is immediately returned to them, and copies filed for use and future reference.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 15.—"The Pigments of the Pieridæ. A Contribution to the Study of Excretory Substances which function in Ornament." By F. Gowland Hopkins.

The wing-scales of the white Pieridæ are shown to contain uric acid, this substance practically acting as a white pigment in these insects. A yellow pigment, widely distributed in the group, is shown to be a derivative of uric acid, and its artificial production as a bye-product of the hydrolysis of uric acid is demonstrated. That this yellow pigment is an ordinary excretory product of the animal is indicated by the fact that an identical substance is voided from the rectum on emergence from the pupa.

These excretory pigments, which have well-marked reactions, are apparently confined to the Pieridæ, and are not found in other Rhopalocera. This fact enables the observation to be made that when a pierid mimics an insect belonging to another group, the pigments of the mimicked and mimicking insects, respectively, are chemically quite distinct.

Other pigments existing, not in the scales, but between the wing membranes, are described, and are shown sometimes to function in ornament. The analysis, and the properties of the yellow scale-pigment are fully discussed in the paper.

Physical Society, November 23.—Prof. Rücker, F.R.S., President, in the chair.—Mr. Womack read a paper on a modification of the ballistic galvanometer method of determining the electromagnetic capacity of a condenser. The condenser is placed in parallel with one arm (S) of a Wheatstone's bridge arrangement of non-inductive resistances. A balance for steady currents having been obtained, the condenser is placed in circuit, and the throw on depressing the battery key determined. The condenser is then thrown out of circuit, and the proportionality of the arms of the bridge disturbed by changing the value of S to S + dS. The steady deflection due to this change is then read. From these two readings and the known values of S and dS the capacity is immediately determined. In practice readings of deflection may be taken with equal positive and negative values of dS. To avoid changes of E.M.F. of the battery, the author finds it best to use a reversing key in the battery circuit, and to observe the throw on reversing the current instead of on simply breaking it. One advantage of the method is that there is no need to know the galvanometer- or battery-resistance, and the author points out that it may be of service in the simultaneous determination of the resistance and of the joint capacity and inductance of a submarine cable or of a telephone or telegraph line. Prof. Perry asked what were the advantages of the method as compared with the Rayleigh-Sumpner method. Mr. Blakesley thought that the correction for damping in the ballistic part of the experiment might be avoided if in the second part the disturbance of balance due to the increment dS were measured by half the first throw of the needle on making the galvanometer circuit, instead of by the steady deflection. He doubted whether reversing the current in the battery circuit would have just twice the effect of simply breaking the circuit. In reply, Mr. Womack said he had not tried the method of reading suggested by Mr. Blakesley, but with regard to the reversing of the battery circuit, that was found to give in practice as nearly as possible twice the deflection which resulted from simply breaking.—A paper, by Prof. S. P. Thompson and Mr. Miles Walker, on mirrors of magnetism, was read by Prof. Thompson. It was pointed out that, corresponding to the theory of electric images produced by insulated conductors, there is a theory of magnetic images produced by bodies of infinite magnetic permeability. A magnet pole in the latter theory is the analogue of an electric charge in the former, and a body of infinite magnetic permeability is the analogue of an insulated conductor (which is electrostatically indistinguishable from a body of infinite dielectric capacity). Experiments were made to determine how far the magnetic images due to thick sheets of iron accorded with those deduced by theory for the case of infinite permeability. The image of a north pole in an infinite plane sheet should consist of a south pole of the same strength at a point coinciding with the optical image of the north pole, together with an equal north pole distributed uniformly over the surface of the infinite sheet, as a free electrical charge would be, and so exerting no finite action. Working at distances of a few inches in front of the surface, a sheet of iron a few feet in length and breadth, and a couple of inches thick, was found to realise the theoretical conditions with very tolerable exactness. In a coil of wire placed on one side of the sheet a current was started or stopped, and the electromotive impulse produced in a subsidiary exploring coil was detected by means of a ballistic galvanometer. That the effect of the actual mirror was equivalent to that of the theoretical image, was verified by substituting for the iron a coil equal and similar to the first, and coinciding with its optical image. Sending the same primary current as before round the two coils (with due regard to its direction in the second coil), hardly any appreciable difference in the secondary impulse was observed. This was found to hold good whether the original primary coil had its axis perpendicular or oblique to the plane of the magnetic mirror. Some observations on spherical sheets were also recorded, but in this case the conclusions were less simple. The paper was followed by a discussion, in which Mr. Boys, Prof. Perry, Prof. Ayrton, Dr. Burton, Mr. W. Bailey, and Prof. Carey Foster took part.—Prof. Ayrton exhibited a student's apparatus for verifying Ohm's law, designed by himself and Mr. Mather. The current flowing through a circuit is to be measured (not necessarily in terms of any defined unit) by means of a galvanometer, while the potential-difference between two fixed points is measured by means of an idiostatic electrometer. Within small limits of experimental error, the current and potential-difference are found to vary in the same proportion; but the electrometer and its manner of use constituted the chief interest of the paper. The fixed and moving parts (inductors and needle) are alike cylindrical in form (the term being understood in its most unrestricted sense), and the generating lines are vertical. There is a vertical axis of symmetry, such that the disposition of these cylindrical parts would remain unchanged if the instrument were rotated through 180° about the axis. The needle is hung by a very thin phosphor-bronze strip, and to obtain a reading when it differs in potential from the inductors by an amount which we have to measure, it is brought back to its ordinary zero position by turning a torsion-head to which the upper end of the suspending strip is fixed. The potential-difference is then proportional to the square root of the angle through which the torsion-head has been turned, but the E.M.F. of a moderate battery of accumulators can be read with very fair accuracy. The authors have bestowed great care on the design of the needle, so that, for a given potential-difference, the turning-moment divided by the moment of inertia may be as great as possible. The whole instrument is protected from external inductive influence by having the inner surface of its glass case coated with a transparent conducting varnish, which Prof. Ayrton has described elsewhere.—Prof. Ayrton also showed an idiostatic electrometer, whose needle, instead of being suspended, was pivoted on an axle. The instrument is rapid and nearly dead-beat in action, and gives a scale-reading of about three inches for an E.M.F. of 100 volts. Prof. S. P. Thompson expressed great admiration for the instruments exhibited, but denied that the law which they served to prove was Ohm's law at all; and this led to some discussion as to what Ohm's law really is. Prof. Ayrton briefly replied.

Chemical Society, November 1.—Dr. Armstrong, President, in the chair.—The following papers were read: The electromotive force of alloys in a voltaic cell, by A. P. Laurie.—Determinations of the E.M.F. developed by sixteen alloys of the heavy metals confirm Matthiessen's conclusion that the tin-gold alloy is the only definite compound amongst them.—A product of the action of nitric oxide on sodium ethylate, by G. W. MacDonald, and O. Masson. Nitric oxide is absorbed by an alcoholic solution of sodium ethylate with formation of an explosive salt, probably the sodium salt of methylenedihydroxynitrosamine, $CH_2[N(NO)OH]_2$. The incomplete combustion of some gaseous carbon compounds, by W. A. Bone and J. C. Cain. When a hydrocarbon containing n atoms of carbon is burnt with n atoms of oxygen, the interaction may be represented by the following equation: $C_nH_x + O_n = nCO + \frac{x}{2}H_2$.—Derivatives of tetramethylene, by W. H. Perkin, jun. A number of halogen and hydroxy-derivatives of tetramethylene and tetramethylenedicarboxylic acid are described. Pentamethylenedicarboxylic acid,

$$CH_2\left\langle\begin{array}{l} CH_2 . CH . COOH \\ \quad\quad\; | \\ CH_2 . CH . COOH \end{array}\right.$$

, by E. Haworth and W. H. Perkin, jun. A number of derivatives of this acid are described.—Substituted pimelic acids, by A. W. Crossley and W. H. Perkin, jun. The authors have succeeded in preparing ethyl- and methylethyl-pimelic acid, and also describe several other new aliphatic acids.—Homologues of butanetetracarboxylic acid and of adipic acid, by B. Lean. The disodio-derivative of ethylic butanetetracarboxylate reacts readily with the alkylic iodides or chlorides yielding derivatives which on hydrolysis are converted into tetracarboxylic acids of the constitution, $CR(COOH)_2 . CH_2 . CH_2 . CR(COOH)_2$; on heating these acids, di-substituted adipic acids are obtained.—Contributions to the chemistry of cellulose. (1) Cellulose sulphuric acid, and the products of its hydrolysis, by A. L. Stern. Cellulose disulphuric acid, $C_6H_8O_3(HSO_4)_2$, is obtained by dissolving cellulose in sulphuric acid; on hydrolysis, it yields first cellulose monosulphuric acid, and then products containing less sulphur.—The chlorination of aniline, by J. J. Sudborough.—Condensation of benzil with ethyl malonate, by F. R. Japp and W. B. Davidson. Benzil and ethylic malonate condense yielding monoethylic benzoïnylmalonate $COPh . CPh(OH) . CH(COOH)COOEt$, and desylenemalonic acid $COPh . CPh : C(COOH)_2$.

Linnean Society, November 15.—Mr. C. B. Clarke, F.R.S., President, in the chair.—Mr. J. E. S. Moore exhibited preparations illustrative of his investigations concerning the origin and nature of the achromatic spindle in the spermatocytes of elasmobranch fishes. His results were approximately in agreement with those arrived at by Hermann in regard to the corresponding elements in amphibia, and more in accord with those of Ishikawa relating to the division of noctiluca. As to the spindle fibres themselves, it appeared that during the diastral stage of the division they were the optical expression of thickenings in the wall of a membranous cylinder stretched out between the chromosomes.—The Rev. G. Henslow exhibited some curious iron implements of somewhat varied pattern, used in Egypt for cutting off the top of the Alexandrine fig, *Ficus Sycamorus*, Linn., the operation being necessary to render it edible by getting rid of the parasitic insect *Sycophaga crassipes*, Westwood, with which it is always infested. The practice was said to be very ancient, being described by Theophrastes, and alluded to by the same word, κνίζων, in the septuagint version of the Old Testament (Amos vii. 14) in translating from the Hebrew.—Mr. H. N. Ridley showed some drawings of the green larva of a sphinx moth mimicking a green tree snake, *Trimeresurus Wayleri*, as well as a cluster of caterpillars mimicking a fruit, all of which were found in Singapore. He also exhibited a drawing from life of the tan-producing gambir-plant (*Uncaria Gambir*) in flower.—Mr. Thomas Christy exhibited some germinating seeds of pepper showing the testa being carried up by the cotyledons.—A paper was then read by Dr. D. Prain, on the plant-yielding Bhang *Cannabis sativa*. Illustrating by lantern slides the anatomy of flower and fruit in *Cannabis*, he reviewed the theories propounded of theirstructure; confirmed from teratology those of Payer (1857) and Celakovsky (1875), and refuted those of B. Clarke (1853) and Macchiati (1889). He then explained (1) the prevention of fertilisation for development of narcotic properties, and (2) of the various forms of the narcotic to each other. A series of monœcious conditions described in plants of both sexes show that the so-called ♂ flower is probably an inflorescence, the perianth segments being bracts, not sepals, while the stamen is the homologue of the anterior sterile carpel of the ♀ flower.—A paper, on the proposed revision of the British Copepoda, by Mr. Thomas Scott, was, in the unavoidable absence of the author, read by the secretary.

Geological Society, November 21.—Dr. Henry Woodward, F.R.S., President, in the chair.—The Pleistocene beds of the Maltese Islands, by John H. Cooke. An especially noticeable feature of these beds is the absence of ordinary anticlinal and synclinal folding, and the predominance of monoclinal faults, which largely affect the character of the surface. These faults were formed prior to the deposition of the Pleistocene beds. The plateaux of Malta, rising to a height of 600–800 feet above sea-level, occur south of the great east-and-west fault, which has a downthrow to the north. They have no Pleistocene deposits upon their summits. Three classes of superficial deposits were described, namely: (1) Valley-deposits; (2) agglomerates and breccias found along coast-lines and fault-terraces, always at the foot of the fault-terraces, or along the lower slopes of the depressed areas; (3) ossiferous deposits of caves and fissures.—Geological notes of a journey in Madagascar, by the Rev. R. Baron.—On a collection of fossils from Madagascar obtained by the Rev. R. Baron, by R. Bullen Newton.

Mineralogical Society.—Anniversary meeting, November 20.—Prof. N. S. Maskelyne, F.R.S., President, in the chair.—The annual report of Council was read and adopted.—The following were elected ordinary members of Council: Prof. A. H. Green, F.R.S., Mr. A. Harker, Mr. A. E. Tutton, and Mr. W. W. Watts, in place of the four retiring members; in other respects the list of officers and Council remains unchanged. The following papers were read: On cone-in-cone structure, by the Rev. Prof. T. G. Bonney, F.R.S.; confirming and extending the views previously published by Prof. Cole.—On a basic ferric sulphate from Parys Mount, Anglesey, by Prof. A. H. Church, F.R.S.; containing the analysis of an earthy mineral corresponding to a compound of one molecule of coquimbite with five molecules of normal ferric hydrate.—Augelite, by Mr. G. T. Prior and Mr. L. J. Spencer; containing a full account of the chemical, physical and crystallographical characters of specimens from Machacamarca, Bolivia, of a mineral previously described only from massive material found in Sweden.—On the occurrence of delessite in Cantyre, by Prof. M. F. Heddle and Mr. J. S. Thomson; containing two analyses of the mineral.—Specimens of augelite, and of a beautiful opal cast of a bivalve from Australia, were exhibited.

PARIS.

Academy of Sciences, November 26.—M. Lœwy in the chair.—Photographic studies of some parts of the lunar surface, by MM. Lœwy and Puiseux. The need of care in interpreting photographs taken under ordinary conditions is emphasised; the many ways in which accidental circumstances may produce markings in the photographic film corresponding to no real object render it essential that the more obscure details shall be fully confirmed by a close correspondence in form and extent on different negatives. Again, the tendency to aggregation of the reduced silver in the negative destroys all value in enlargements carried beyond a certain limit, say thirty or forty times the original size. Certain clear negatives, obtained at Paris on February 13 and March 14, have been enlarged by Dr. Weinek and compared with the best maps of the corresponding region, with the result that many new details, fully described in the paper, have been added to our knowledge of the moon's surface.—A note on the calculation of the orbits of planets, by M. F. Tisserand.—An observation of Wolf's planet (1894, B E), made with the Bordeaux equatorial, by M. G. Rayet.—On the laws of air resistance, by M. E. Vallier. Formulæ are derived which express the specific resistance of air to a moving body (*a*) where the velocity is greater than 330 metres, (*b*) where the velocity is between 330 and 100 metres, and (*c*) where the velocity is less than 100 metres per second.—New details concerning the Nymphæinæ; tertiary Nymphæinæ, by M. G. de Saporta.—The elements of the planet B E, by M. L. Schulhof.—Observations of Swift's new comet E (1894, November 20) from the Paris Observatory, by M. G. Bigourdan.—On the distribution of planets between Mars and Jupiter, by M. E. Roger. A mathematical paper in which the author endeavours to obtain, from the known distribution of the minor planets, some support for a hypothesis formulated in a previous communication (*Comptes-rendus*, t. cxvi.).—On the movement of a solid body, by M. G. Kœnigs.—On an application of the principle of areas, by M. L. Lecornu.—On functional equations, by M. Leau.—On Bertrand's theorem, by M. Cartan.—A *réclamation* concerning M. P. Stäckel's note on the problems of dynamics of which the differential equations admit an infinitesimal transformation. M. Otto Staude published a paper on this subject in 1892. M. Stäckel merely extended the theorems therein demonstrated from two and three to *n* variables.—On the tempest of November 12, 1894, by M. Alfred Angot. A tabular comparison is made between data obtained at the Meteorological Bureau and on the Eiffel Tower respectively. Interesting conclusions are drawn from the tower observations, which are free from the disturbances ordinarily brought in owing to the nearness of the surface of the soil.—On the conversion of propionic acid into lactic acid, by M. Fernand Gaud. By heating a mixture of 10 per cent. of propyl alcohol with Fehling's solution for 200 hours at 240°, the author has obtained both the ordinary and isomeric lactic acids. As metallic copper is produced on heating copper propionate with excess of water at 200°, the equation representing the production of the lactic acid must be written $2(C_3H_5O_2)_2Cu + 2H_2O = 2Cu + 2C_3H_6O_3 + 2C_3H_6O_2$.—On the ethereal salts derived from active amyl alcohol, by MM. Ph. A. Guye and L. Chavanne. The specific rotations are given for a number of these esters, the maximum value is obtained for the fatty salts with amyl propionate. The product of asymmetry reaches its maximum with amyl acetate.—On the so-called organic chlorine of the gastric juice, by M. H. Lescœur. A direct method of determining *organic chlorine* is described, and it is pointed out that the *organic* chlorine of MM. Hayem and Winter is partly derived from ammonium chloride, which is itself partly formed at a high temperature from the sodium chloride present.—On the composition of the red pigment from *Diemyctylus viridescens*, by M. A. B. Griffiths. The analytical results give the formula $C_{20}H_{18}N_2O_7$ for die nyctyline.—On acid leathers, by MM. Balland and Maljean.—A new entoptical phenomenon, by M. S. Tchiriew.—The principles of chroology or physiological synthesis of colour, by M. W. Nicati.—On the effects of ablation of the venom-glands in the viper (*Vipera Aspis*, Linn.), by MM. C. Phisalix and G. Bertrand.—Contributions to the study of the "cellule conjonctive" in the molluscous Gasteropods, by M. Joannes Chatin.—A new method for the cultivation of fish-ponds, by M. Jousset de Bellesme.—The reptiles of the upper jurassic age in the Boulonnais, by M. H. E. Sauvage.—On the new ivory human statuettes from the quaternary station at Brassempouy, by M. Ed. Piette.—Influence of arsenic acid on the growth of algæ, by M. Raoul Bouilhac. It is shown that arsenic acid in certain cases acts like phosphoric acid, which it may replace in some plant cultivations.—On the age of Lake Bourget and the ancient alluvial deposits of Chambéry and the valley of the Isère, by M. A. Delebecque.

DILETTANTISM AND STATISTICS.

The Growth of St. Louis Children. By William Townsend Porter. Vol. vi. No 12: Transactions of the Academy of Science of St. Louis.

THE anthropometrical researches of Mr. Francis Galton have had a very widespread influence, and, under his inspiration, a large mass of material has been, and is being collected, which cannot fail to be of service in elucidating a number of knotty problems. In particular, very comprehensive measurements of children have been made in America by Bowditch, Sargant, and Porter, the results being tabulated by aid of Mr. Galton's method of percentiles.

It is not only in the form of statistics of measurements on man, but also of measurements on the lower animals and on plants, that material for the study of variation and correlation is accumulating with almost alarming rapidity. We say with almost alarming rapidity, for not only is theory lagging somewhat behind the needs of statistical experience, but, what is far worse, many collectors have no real insight into the theory which does exist. They are tabulating results in a form which will be of no permanent service, or neglecting to publish the very details which alone would enable us to test any development of statistical theory. The ignorance of the elements of mathematics, to say nothing of the theory of chance, is, indeed, singularly characteristic of many investigators, who think statistics can be handled, and conclusions drawn from them, without the least preliminary training. For example, in a recent paper on variation in the flowers of buttercups and clover, by Herr de Vries, we are introduced to our old friend the normal curve of errors as a definite symmetrical polygon; no attempt is made to fit it by aid of the probable error of the observations, but a particular form of it, apparently selected at random, is plumped down on the top of another polygon representing the observations. The odds against the thus selected theoretical polygon (curiously called the "Galton Curve") expressing the real distribution of variation, are, it is needless to say, many thousands to one. Still more curiously, sets of observations giving theoretically very good frequency curves of the type which occurs in infantile mortality, the valuation of houses, &c., are termed "Half-Galton-Curves," although the type, so far from being represented by the half of the normal curve of errors, corresponds to a curve asymptotic to the ordinate of maximum frequency! We might pass these eccentricities by, were not statistics thus handled used to support some vague theory of heredity, or to question some principle of variation.

Mr. Porter is not quite so wild in theory as Herr de Vries, but for him also the normal curve of errors appears to be a polygon, and he tells us, on p. 277, after a table of its ordinates—which are quoted from Thoma, and given only to the units, and *not to decimals*—"that there is a limit beyond which no deviation occurs." It is, perhaps, needless to say that if we start only with a knowledge of the theory of chance, such as may be found in works like those of Thoma and Stieda, we are hardly likely to avoid bad theoretical blunders. Mr. Porter is no worse than many writers of memoirs in the *Journal of the Royal Statistical Society;* but the time has come when statistics, as well as archæology, must be taken out of the hands of the dilettanti, and when a man, if he takes upon himself to publish statistical researches, must, like the physicist, show his credentials in the form of a fair mathematical training.

Unfortunately, Mr. Galton's method of percentiles, useful as it is in the right place, is now acting as a distinct check to statistical theory in a somewhat unexpected manner. Before that theory was disseminated the dilettante statistician was compelled to publish his raw material, and his remarks on it did not impair its value to the trained scientist. Now, however, the percentile method of dealing with statistics seems so intelligible, that the non-mathematical anthropologist or physiologist grasps it at once, reserves his raw material, and publishes tables of percentiles. It is hard to conceive anything more disastrous for true statistical progress.

The reason for this is easily explained. As is well known, any normal curve of errors can be reduced to any other by uniform stretches (or squeezes) parallel to its base and its axis. The area of any portion of any normal curve up to a deviation of given magnitude cannot be given by a finite series; it can by stretching be reduced to an integral, the values of which are tabulated, but which is not itself finitely expressible for an indefinite value of the deviation. The tables formed of this integral, however, enable us to pass from selected percentiles to the constants, and so to the form of the frequency curve. Now, innumerable frequen cy curves in biological, just as in econom ical statistics, are *not* of the normal type. A generalised frequency curve can be theoretically obtained fitting closely the observations in many, perhaps in all such cases, but owing to its asymmetry or skewness, its limited range and other features, it neither possesses the stretch property of the normal curve, nor can its areas be expressed by tables of one entry. The tables required are, according to the type, of two or three entries, and such tables are not likely to be prepared for a long time to come, and if prepared, would be of little service except for the case when the statistics are given in percentiles. In other words, the use of percentiles may suffice to demonstrate the skewness of the statistics, but at once precludes the use of any theory higher than that of the normal curve, by which the skewness could be accounted for. This is the fundamental defect of Mr. Porter's labours. He gives us a most extensive system of measurement on boys and girls from six to twenty years of age—ample material, if properly dealt with, to provide solutions for innumerable problems in correlation and selection with age. The material, however, is only given in the form of percentiles or in diagrams of the "ogive" curve corresponding to the integral of the frequency curve. These diagrams fully confirm the results of Bowditch—*that the statistics are skew, and that the degree of skewness varies with the age.* But all means of scientifically treating this skewness disappear, because we have only percentile results. The skewness of the original frequency curve cannot be deduced from nine or ten points on a curve, the equation of which is only expressible by an unintegratable form containing the con-

H

stants to be determined. This is all the more tantalising, as the variation with age (or with selection) of the skewness of the frequency curve for a given organ is very probably a most important factor in the mathematical treatment of evolution, while it is precisely *human* material which enables us to record the age, too often an unknown quantity in investigations on the lower animals. It must not be supposed, however, that Mr. Porter realises that skewness in the percentiles marks want of normality in the frequency curve. On the contrary, he takes the raw material for the height of 2192 girls aged eight, and fits it, not very accurately, to a normal frequency distribution. Although the measurements better fit a skew than a normal distribution, the divergence from the normal is not very marked, and Mr. Porter writes:

"It is not necessary to make this comparison at more than one age, or in more than one dimension, for it is known that if one series in a group like that with which we have to deal shows this agreement, the other series will be found to do the same." (p. 290.)

Now the whole point of the measurements, if properly interpreted, is to ascertain the varying degree of skewness with age, *i.e.* the varying amount of divergence from the normal curve. To emphasise this divergence when remarking on his raw material, but to fail to recognise what bearing it has on theory, is typical of the untrained statistician.

As we have seen, the use of percentiles renders Mr. Porter's material of small value for the problem of selection. The same remark again applies in the case of correlation. The ten organs measured would have been most valuable material for the problem of correlation; the percentile results alone being given, nothing can be done. In Chapter ix. Mr. Porter does develop a theory of correlation, which, however, seems to us absolutely erroneous. As he makes it the basis of a scheme for the school physician to testify whether the pupil's strength is equal to the strain put upon it, this want of accurate theoretical knowledge appears doubly unfortunate.

We have ventured to point out these failings in Mr. Porter's work, not because they are peculiar to him—they are characteristic of much work of a statistical kind which is now being turned out in both Europe and America—but rather because they point to a new need, which the public has hardly yet recognised. There has been up to the present time—with the honourable exception of courses of lectures by Dr. Venn in Cambridge—no teaching of statistical theory in England. There is no chair of statistics in any English university, and the Newmarch lectureship at University College, except for the year of its tenancy by Prof. Edgeworth, has been held by economists, and not by mathematically trained statisticians. We want a centre, which shall not only contain a statistical museum, but embrace as well a statistical laboratory and workshop. In such a centre students might not only receive a mathematical training in dealing with raw statistics, but also be exercised in the methods of collecting and tabulating, which must precede mathematical reduction. To such a centre the biologist and anthropometrist could send their measurements to be "fitted," the physicist his observations to be dealt with, and the economist or sociologist his price or labour statistics to be analysed. At the same time, absolute measurements might be made bearing on the problems of evolution, disease and national economy. In this manner a number of efficient young statisticians might be trained, who would not only find a life-work ready for them in craniology, zoology, botany, and economics, but who, passing into government departments, census offices and labour bureaus, might remove from us the reproach of a recent continental writer, that nowhere were statistical dilettanti so rampant as in England.

KARL PEARSON.

WATER SUPPLY AND WATER-WORKS.

The Principles of Water-works Engineering. By J. H. Tudsbery Turner and A. W. Brightmore. (London: Spon, 1893.)

The Water Supply of Towns. By W. K. Burton. (London: Crosby Lockwood and Son, 1894.)

WITH the constant growth of population, and the increasing tendency of the population to congregate into large towns, the provision of an ample supply of pure water to towns becomes every year of greater importance; whilst, as the nearer sources of supply become inadequate for the ever-growing demands, a sufficient supply becomes more difficult to obtain, and has to be sought at considerable distances. Accordingly, the subject of water-supply has assumed an enhanced importance within recent years; and till these books appeared, there was a dearth of comprehensive text-books on this branch of engineering. As the sources of water-supply, and the works for its provision and distribution are comprised within very definite limits, both books necessarily traverse much the same ground, and deal with similar classes of works; but, nevertheless, they exhibit differences in arrangement, and in the method of treating the various subjects. Thus, whereas "Water-works Engineering" extends over 420 pages, separated into only eight chapters, and illustrated by one hundred and twenty figures in the text, "The Water Supply of Towns" is subdivided into twenty-two chapters, occupying only 272 pages, somewhat larger in size, but illustrated by two hundred and fifty-seven drawings, several of which are put into forty-three large folding-plates. The first book, moreover, is subdivided into numbered sections, the numbers of which are merely used for reference, and instead of the pages in the index; whilst the various subjects in the second book are clearly indicated by black-letter headings. Altogether, "The Water Supply of Towns" is much better arranged for reference; and though containing slightly less matter, it is much more fully illustrated, is in larger print, and has a somewhat longer index than "Water-works Engineering." Neither book gives a summary of contents at the head of each chapter, which is often serviceable for reference.

In "Water-works Engineering," the sources, measurement, collection, storage, purification, conveyance, and distribution of water, and the maintenance of water-works, are successively dealt with in the eight chapters. The most logical sequence would be to describe in regular order the various processes to which water is subjected, from its source up to its delivery to the consumer.

This has only been partially accomplished in "Water-works Engineering," for, owing to the small number of chapters, such dissimilar subjects as the available rainfall and the gauging of the flow of streams have been put in the same chapter, near the beginning of the book, with water-meters, which latter subject should properly have been dealt with at the end, in connection with consumption and waste. Moreover, impounding reservoirs and dams are grouped with service reservoirs, tanks, and house cisterns; whilst the filtration, purification, and softening of water, are considered before the preliminary process of conveyance from the source of supply by aqueducts and conduits. Though the grouping of dissimilar subjects has been avoided in "The Water-Supply of Towns" by the multiplication of chapters, the natural sequence of processes has not been always maintained; for the chapters on pumping machinery, and the flow of water in conduits and open channels, follow after the chapters on purification; whereas the flow of water is intimately connected with the conveyance of the supply from impounding reservoirs; and purification and softening are more needed for waters pumped out of rivers, or from wells, than for waters impounded in a reservoir in a mountainous uninhabited district. In this book, however, the descriptions of water-meters are given in the chapter on the prevention of waste of water, to which subject they properly belong; and cisterns are referred to in this connection, as well as in relation to distribution.

The most notable difference between these two books consists in the use made of mathematical calculations and formulæ. Prof. Burton rarely introduces any formulæ, contenting himself, in the case of high masonry dams, with diagrams of the theoretical profiles proposed by Prof. Rankine and Mr. Wergmann, in addition to the actual sections of the Vyrnwy dam in Wales, and the Tytam dam at Hong Kong; whilst he refers his readers to Fanning's "Treatise on Hydraulics and Water-works Engineering" for formulæ relating to the flow of water. A less cursory treatment of these important subjects, in relation to water-supply, might reasonably be expected in a book which is stated, on its title-page, to be "a practical treatise for the use of engineers and students of engineering"; but perhaps Prof. Burton exercised a wise discretion in this matter, for in the calculation of the cross-section of a stream, on page 28, he falls into an obvious error in including the depths at both extremities to obtain the average depth. The authors of "Water-works Engineering," on the contrary, incline towards the other extreme, and devote more attention to mathematical solutions than to practical considerations. Some amount of mathematical treatment is unquestionably expedient in dealing with the flow of water and the design of masonry dams; and formulæ based upon experience, together with diagrams, furnish almost indispensable aids in the consideration of these matters, and for their practical application. It is, however, an undue extension of the province of mathematics, in such a treatise, to use them to prove that impalpably fine matter in suspension in water would never fully settle (pp. 266–7), which is a subject for physical experiment; and the result would vary with the nature of the material and its specific gravity. Moreover, considering the uncertainties that exist as to the precise distribution of the pressures over the masonry of a reservoir dam, it appears somewhat superfluous to devote over two pages in calculations proving that wind-pressure against the outer face of a masonry dam has only a very slight influence in modifying the position of the line of resultant pressures, with the reservoir empty, under the exceptional conditions of a high wind blowing up the valley, and the reservoir being empty. The somewhat free use of mathematical processes, and the occasional introduction of the integral calculus, will unfortunately be liable to deter persons, who have not received a regular mathematical training, from consulting "Water-works Engineering"; though the greater part of the book deals clearly and concisely with the practical matters and works relating to this branch of engineering. More frequent references to executed works, by way of illustration, would have added interest to the book, and would have served to exhibit the methods of application of general principles, and their results; but the authors explain in their preface, that they considered descriptions of works outside the scope of their book. Owing doubtless to their having lived in cities supplied from wells and impounding reservoirs, they condemn the quality of river waters in stronger terms than the inhabitants of London, deriving a large proportion of their supply from the Thames, would be prepared to admit as correct. They say: "The quality of river-water is seldom unexceptionable, and is frequently bad. . . . Rivers are generally charged with impurities of vegetable, animal, and mineral origin, to such an extent as to render them frequently a most desirable source of water for irrigation purposes, but not for domestic supply." After this it is only a slight consolation to be told that, "still, by certain processes, even the most unpromising river-water is often rendered generally serviceable," especially as, shortly after, they quote the statement of the Rivers Pollution Commission of 1868, that "there is no river in the United Kingdom long enough to effect the destruction by oxidation of sewage put into it at its source," and add, in conclusion, that "the result of the aëration produced by even the Falls of Niagara is so insignificant as to be insensible so far as regards any purifying effect upon the water."

As the author of "The Water Supply of Towns" is Professor of Sanitary Engineering in the University of Tokyo, he has naturally inserted some matters relating more particularly to Japan, such as, for instance, certain special provisions for the extinction of fires which are very common in Japan, owing to the light construction of the houses, and more especially the probable effects of earthquakes on water-works, and the precautions to be taken against them. Most, however, of these special matters have been relegated to foot-notes and an appendix; whilst some particulars of general interest relating to the Tokyo water-works are given in the text.

Both books contain a fairly complete exposition of the principles relating to the water supply of towns, and a general description of the construction of water-works; and they should both prove valuable to the engineer and the student, in relation to this special branch of engineering. Whilst, however, the engineering student, who has had the advantage of a mathematical and scientific training, will doubtless prefer the more scientific metho exhibited in "The Principles of Water-works Engineering," the practical engineer will obtain fuller information, with less trouble, from the more clearly arranged and better illustrated pages of "The Water Supply of Towns."

HAMILTON'S PATHOLOGY.

A Text-book of Pathology, Systematic and Practical. By D. J. Hamilton, M.B., F.R.C.S.E., F.R.S.E., Professor of Pathology, University of Aberdeen. Vol. ii. Parts 1 and 2. (London: Macmillan and Co., 1894.)

THESE two handsome volumes complete the laborious task which Prof. Hamilton set himself many years ago, of producing a text-book of pathology, which should include not merely morbid anatomy and histology, but should deal also with clinical medicine, and those new but rapidly developing sciences, pathological chemistry, pathological physiology, and bacteriology.

It is true that the many varied problems which come before a pathologist require for their solution a more or less extensive acquaintance with each and all of these branches. So many, however, are the workers, and so vast has the literature become in each branch, that it is already impossible for anyone to be equally proficient in all, and it is necessary to specialise.

If this is the case with the individual, it is much more so with the text-book. It is impossible to compress within even 1800 pages, a tithe of our present knowledge of all these branches, and opinions will differ widely as to how the selection should be made.

The task of making such a selection is herculean enough to daunt any man, and the thanks of all interested in pathology are due to the Professor for the very valuable addition he has made to our literature on the subject. The amount of original work is considerable, and the volumes are copiously illustrated by drawings, the majority of which are by the author.

An extremely useful feature in the book consists in the bibliography of both the English and foreign literature at the end of each section. The convenient system is also adopted of indicating the title of any publication referred to in the text by a number in Roman letters, while the full titles and the corresponding numbers are given in a list at the end of the book. The first volume, which was reviewed in these columns in 1889, met with general appreciation. This volume commenced with full directions for making systematic post-mortem inspections, and for the practical bacteriology and histology of the tissues removed. Nearly 200 pages were devoted to a full account of inflammation and suppuration, and of tumours and new formations, while the remainder of the book was occupied by an account of the heart, the blood, and the vascular system generally.

The two parts of the second volume now issued are bound up separately. The first part of the present volume is devoted to a systematic account of the pathology of the respiratory organs, the liver and the kidney; a good solid piece of work containing much original research, in which are embodied the well-known papers of the author on diseases of the lungs, and on cirrhosis of the liver. Among the many observations, we would draw attention to the important conclusion that in nephritis the fatty granular remains of the convoluted epithelium are absorbed by the lymphatic system, and are not, as is generally supposed, mainly washed out by the urine.

The drawings, illustrating the author's views, are worthy of all praise; they are well executed, and are sufficiently diagrammatic to impress the conclusion to be indicated, while their reproduction also reflects great credit on the publishers.

The remainder of the volume deals with the diseases of the digestive, the nervous, the osseous and the cutaneous systems, finishing with a short statement of the various malformations, and a good summary of systematic bacteriology and of human parasites.

The present volume is overweighted by 150 pages of normal anatomy and physiology, which preface the accounts of the various organs, nearly fifty pages and twenty illustrations being devoted to the nervous system. This material is surely out of place in a book, in which the author has been compelled by the exigencies of space and time to reduce his account of the pathology of many conditions to too brief an account to be of value, so that often there is no indication as to which lesions and causes are common and important to remember, and which are exceptional; frequently a mere list of them is given.

It is also to be regretted that it has been thought desirable to devote valuable space to the description of the various tests for sugar and albumen in the urine, as this information is contained in the ordinary standard books on clinical medicine.

The author apologises for the lapse of five years since the appearance of the first volume; and we cannot help regretting that Prof. Hamilton did not publish only the first part of the present volume, and allow himself another year or more in which to have worked up the second part to the high standard reached in the earlier portion of the book. Although five years may appear a long time, for the production of the second volume of this book, still the amount of labour required was so extreme that more time was really necessary. The lack of space also has necessitated so much compression, that often the pathology is reduced to a mere explanation of the terms used; while the numerous omissions of important facts suggest that this part has been produced at very high pressure, so that the facts are not presented in their due relation to one another, while there are several statements to which we would take exception.

While such common causes of optic neuritis as plumbism and anæmia are omitted, excessively rare ones, such as pneumonia and measles, are given; again, while optic neuritis is discussed, optic atrophy is omitted. Among the causes of cerebral hæmorrhage, such well-recognised ones as glioma and aneurysm are omitted.

Through oversight the following conflicting statements have been allowed to appear. Under cysts of the liver, the association of such with similar ones in the kidney is said to be fortuitous; while under the head of renal diseases, it is noted that out of sixty-two cases of cystic kidneys, seventeen were associated with similar cysts in the liver. On one page, in discussing the growth of typhoid bacilli, great doubt is thrown on whether they spore; on the next page, it is stated that they invariably spore when grown under suitable conditions.

The excellence of the work, and it is great, lies in the histological and bacteriological portions, and in the numerous and ingenious theories and suggestions; but the necessity of finishing the book soon, and of keeping it within reasonable size, appear to be responsible for the less satisfactory accounts of the morbid anatomy and of the etiology of the lesions in certain of the sections. This, however, will probably be remedied in later editions.

OUR BOOK SHELF.

The Mechanism of Weaving. By T. W. Fox. Pp. 464. (London: Macmillan and Co., 1894.)

ONE result of the application of the "beer money" to education is the increasing production of technical handbooks similar to that before us. Technical Instruction Committees found, very soon after their responsibilities were thrust upon them, that there were few competent teachers of technology, and that the literature of arts and crafts was very limited. Many books have been made for the purpose of supplying the need, some good and others of doubtful utility. The new conditions have been favourable to the development of technological books and teachers, and we must not complain if a few monstrosities occur in the case of each, for they are more than counterbalanced by many admirable examples on the other side. The book under review is one of these new guides to industries, and nothing but good can be said of it. It deals with a branch of weaving that has been almost ignored by previous writers. Much has been written on designing and fabric structure, but practically nothing on the mechanical processes of the weaving trade, though new machinery and new processes have been increasing ever since the power-loom supplanted the hand-loom. This gap is admirably filled by Mr. Fox's treatise. The leading types of weaving machinery are clearly described, and the numerous illustrations (256 in all) of machines, appliances, and constructions pertaining to the textile industry are most instructive. We have no hesitation in saying that Mr. Fox, who is the lecturer on textile fabrics at the excellent Municipal School at Manchester, has produced a practical handbook of great value.

Memorials of Old Whitby. By Rev. J. C. Atkinson, D.C.L. Pp. 326. (London: Macmillan and Co., 1894.)

FICTION, "like the baseless fabric of a vision, leaves not a wrack behind," because it has no foundation in fact. Stories that are commonly classified as "fabulous" usually have, however, a nucleus of scientific import. In the words of Canon Atkinson: "The myth, the fable (of the mystic sort), the legend, has always a base, a substratum or foundation of some sort. Like the Pentacle, with its mystic application and use, or the Svastika, Fylfot, or Hammer of Thor, the Monolith or Standing-stone—from Jacob's stone at Bethel, and before and since—it has always had its own something to rest upon, to spring from its actual material 'base' or occasion." Scientific inquiry is required to reveal this base; but by this we do not mean that facts of physical or of natural science are necessarily involved in every marvellous story, but rather that the investigator of legendary lore should conduct his research in a scientific spirit, discarding speculative evidence, and reducing the problem to its simplest appearance. This is the spirit in which Canon Atkinson has investigated the myths, legends, and traditions connected with Whitby. His treatment of the Caedmon legend is worthy of special mention. It will be remembered that Caedmon produced his great sacred poem at Whitby. According to Baeda, he was a common cowherd or oxherd, to whom the gift of poesy was miraculously, or at least suddenly, given, and this story has been generally accepted in spite of its great improbability. Canon Atkinson rids the story of its miraculous element, and justifies the dictum *poeta nascitur, non fit.* He shows that it is largely mythical, and that Caedmon was probably a homely native poet of some genius, but undeveloped, before the Abbess Hild took him up. This view is practically clinched by the evidence that Caedmon's name is of Celtic origin, and that therefore he doubtless possessed the fervid imagination and vivid fancy of the Celtic temperament. It need hardly be said that the miracle described by Baeda would have been eliminated from the story at once by a man of science. To us it seems that Canon Atkinson comes to the only conclusion possible after a careful consideration of historical records, and a common-sense view of the case. Other stories and customs connected with Whitby are discussed with a similar broad-mindedness, and in a manner which local historians generally would do well to follow.

Die Schöpfung der Tierwelt. Von Dr. Wilhelm Haacke. Pp. 552. (Leipzig and Vienna: Bibliographisches Institut, 1893.)

IT is just as well to state at once that this is a scientifically-arranged description of the animal kingdom, profusely and beautifully illustrated with twenty coloured plates and 469 figures in the text. The illustrations are certainly among the finest of their class, and one cannot help regretting that, as the text is in German, the work can only have a limited sale in England. We can console ourselves, however, with Mr. Lydekker's "Royal Natural History," now being published, and which is rather more popular than the volume under review. The order in which Dr. Haacke treats his subject is uncommon. The book is divided into two parts, one dealing with the various forms of animal life from the point of view of their development, while in the second part the characteristics of different groups of animals are described. The first part is thus chiefly concerned with embryology and palæontology in their relations to zoological affinities; with the functions of organs and the influence of environment; and with the distribution of animal life upon the earth. In the second part, invertebrated and vertebrated animals occupy two separate sections, and life is traced from the protozoa up to the higher forms. From this brief sketch it will be seen that the book has the theory of evolution as the basis of its construction. It is therefore a work in which the facts of natural science are presented in scientific order, and as such deserves high commendation.

The Vaccination Question. By Arthur Wollaston Hutton, M.A. Pp. 128. (London: Methuen and Co., 1894.)

MR. HUTTON is among the mistaken people who distrust vaccination, and advocate the repeal of the compulsory laws relating to it. His book is in the form of a letter addressed to Mr. Asquith, in the hope of converting him to the opinion that compulsory vaccination is indefensible. It would be futile for us to discuss the subject, or to attempt to show the fallacy of much of the evidence adduced against vaccination. We may, however, point out that, to be consistent, the anti-vaccinationists must oppose the treatment of diphtheria by anti-toxic serumt; but this they are doubtless ready to do.

Dr. William Smellie and his Contemporaries. By John Glaister, M.D. Pp. 360. (Glasgow: James Maclehose and Sons, 1894.)

DR. GLAISTER'S book throws some new light upon the history of obstetrics in Great Britain and France, during the eighteenth century, in addition to tracing the career of one of the founders of scientific midwifery.

Smellie's work, however, was so purely medical in character, that a review of it would be of little interest to most of the readers of NATURE.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Dr. Watt's Dictionary of the Economic Products of India.

THE notice of this important undertaking in a recent number of NATURE (November 1, p. 4), seems to me somewhat unsympathetic, and scarcely to do justice to its undoubted merits. At any rate, the Government of India, at whose instance the Dictionary was prepared, might draw the conclusion from the review that the work was more open to criticism than I believe to be really the case. A British Government is never too ready to undertake an enterprise of this kind, and anything of the nature of a disappointment, when it has made the experiment, is little likely to induce it to make another.

As I warmly encouraged the inception, and have taken a keen interest in the progress of the Dictionary, I feel bound to express my opinion that it is one of the most important aids which has yet been given to the material advancement of India.

As the reviewer correctly remarks, "the large proportion of the products" of that country "are of vegetable origin." It is, however, astonishing how little they are known in Europe. I can speak with some confidence on this subject, because, in 1880, the India Office transferred to Kew the entire economico-botanical collections forming part of the India Museum at South Kensington. Their incorporation with the existing contents of the Kew Museum was carried out under my supervision. I was struck, as every one has been who has had to do with the subject, with the profusion of products for which some useful purpose ought to be found in the arts. As Kew undertook the duty of acting as referee with regard to these matters, it became necessary to accumulate information with regard to them. I therefore formed in my office a sort of rough dictionary, in which I posted up every paper, document, and scrap of information which I could collect about Indian vegetable products. This enabled me to deal rapidly with a great number of commercial inquiries. But for this purpose, Dr. Watt's Dictionary is an infinitely superior instrument. It is in constant use in my office, and I am at a loss to conceive how the day's work could now be got through without it. As I am continually testing its contents, I can only express my surprise at the degree of accuracy which Dr. Watt has attained. I am quite satisfied that the catalogue of not very important blemishes which the reviewer has managed to detect, must have cost him no small labour. The criticisms, with one exception, I do not propose to discuss. I cannot help, however, regretting that the reviewer both begins and ends his article with something like a sneer—in the one case at the size of the book, in the other at the paper on which it is printed.

Such an encyclopædia of economic products as the Dictionary affords, has long been needed. Indirectly I regard it as one of the outcomes of the Famine Commission, the second part of whose Report was presented to Parliament in 1880. In this Report (p. 175) the Commission point out that "at the root of much of the poverty of the people of India . . . lies the unfortunate circumstance that agriculture forms almost the sole occupation of the mass of the population." "Facilities for obtaining profitable markets for all sorts of produce" is a necessary means of remedying this state of things. But it is obvious that the markets will not come into existence till the products are brought into demand by better knowledge.

The bulk of the book and the length of the articles was, I imagine, the result of a deliberate plan on the part of the Department of Revenue and Agriculture under whose authority the Dictionary was issued. One object in view was to afford to Indian officials, who cannot be expected to take a miscellaneous library about with them, a standard book of reference. The want of something of the kind led Mr. Edwin T. Atkinson, of the Bengal Civil Service, to commence a sort of industrial survey of the north-western provinces. The work is only a fragment, as Dr. Watt's Dictionary has since covered the ground. The preface to the first part (Allahabad, 1876) puts the needs of Indian officials so clearly, that it will be useful to quote from it:

"There is no subject perhaps regarding which so much has been written and spoken as 'the development of the resources of the country.' The phrase is a pretentious one, and has a rounded, rolling sound worthy of many of the ideas launched in its name, but really expresses what must form one of the first duties of every civilised Government. As early as June 1804 a Mr. Gott was deputed to examine the forests of Rohilkhand and Gorakhpur, with the view of ascertaining what local products could be advantageously brought to the notice of the European world. . . . He was followed by Laidlay and others, who examined into many of the questions which even now are made the subjects of inquiry. Their reports lie unused and unknown amid the twelve hundred volumes of records composing a portion of the immense library of our Board of Revenue, and surely it would be a saving of money and labour if these reports were given to the official and non-official public. My own inquiries have shown me that it is the tendency of all these questions to crop up in cycles, with the same result, the same perfunctory procedure; and were official memory long enough to recollect what has already been done, and know where to find it, one half of the erratic circulars which now puzzle and worry the district officers, might be answered by a reference to the correspondence on the same subject. . . . A review of the efforts made in the past to attain a knowledge of the resources of the country is not unmixed with regret. They have all gone by without leaving any trace behind them, and without advancing our knowledge one single step, because they wanted organisation."

In criticising Dr. Watt's Dictionary, a statement like this should be borne in mind. Dr. Watt has, in fact, and it is one of the great obligations we owe to him, gutted and boiled down the colossal and inaccessible official literature of India. For the first time, an Indian official has at hand all that is practically to be said about any local product with which he has to deal.

These points were, I think, not clearly brought out in the review in NATURE, and I think it is only due to the Government of India that they should be stated.

There is one detailed criticism on which I absolutely take issue with the reviewer. He devotes some space to the expression of the opinion that with regard to "drugs and therapeutics, the details are out of place in a description of economic products." He particularly objects to the inclusion of plants, "solely because of some medicinal, or supposed medicinal, use, frequently by ignorant people." To me the subject seems, on the contrary, of the deepest importance. It is the empirical knowledge acquired by "ignorant people" which is at the base of almost all our knowledge of drugs. And the extension of modern therapeutics must in the main depend on following up the beginnings in new directions which ignorant people have made. In this respect the Dictionary is a mine of information available for the guidance of future research. In India itself a trustworthy account of the properties of the plants used by the natives for therapeutic or even criminal purposes, must, it seems to me, be of every-day utility.

W. T. THISELTON-DYER.

Royal Gardens, Kew, December 8.

IN your recent review of the above work, attention is drawn to the startling statement that "Diamond dust is known to be a powerful mechanical poison." This statement, occurring as it does in an official work, issued by the Government of India, aroused my amazement when I first had occasion to consult the Dictionary. It occurred to me then, and I still think, that the author would have done better to have quoted the words of Colonel Wilks on the subject ("South of India," vol. ii. p. 197), namely, "Whatever doubts may be entertained of the fact, there is none regarding the belief [by the Mahommedans of Southern India in the power of diamonds as a poison], and the supposed powder of diamonds is kept as a last resource like the sword of the Roman, but I never met with any person, who from his own knowledge could describe its visible effects, &c."

Better still perhaps, instead of giving what, as you have pointed out, is an erroneous account of the celebrated Gaikwar's case, Dr. Watt might have quoted the emphatic words of the Commissioners who tried the Gaikwar, that "Diamond dust according to the best authorities has no injurious effect on the human body" ("Commission Report," p 223).

With some inconsistency—although Dr. Watt quotes an account of the reputed medicinal qualities of prepared diamond

—he does not follow up the first statement by including it in his list of reputed poisons (vol. vi. p. 309.) It may be added that Dr. Watt's selection of authorities, generally, appears to be somewhat capricious. He does not appear to be acquainted with Garcia de Orta's famous work on Indian drugs, for he gives Linschoten and others credit for observations not originally made by them, but by Garcia, *e.g.* art. *Manna.*

Again, when writing of ambergris, surely he might have found some more direct source of information regarding a product derived from *whales*, than a work, excellent though it be, which deals properly with the products of the Punjab.

I write as one not wishing to find fault, especially as I recognise the good services done by Dr. Watt, but because I believe such a work so brought out, should be a faithful summary of recorded facts, which, if hitherto only known to comparatively few, should be so stated as not to mislead the many who may have occasion to refer to the Dictionary. V. BALL.

Science and Art Museum, Dublin, November 19.

Drift-Bottles in the Irish Sea.

IN NATURE for Nov. 8 (p. 35) mention is made of the travels of some drift-bottles in the south seas. It may be of interest to put on record the results so far obtained of the distribution of bottles set free by the Liverpool Marine Biology Committee in order to get further information in regard to those currents in the Irish Sea which would affect small floating bodies. The objects we have had in view are: (1) A purely scientific matter, the source and distribution of the plankton; and (2) the probably utilitarian object of determining the movements of the food of fishes, and so one of the causes of their migrations, and also the drift of the floating ova and embryos of food fishes. The tidal currents of the area in question are to a considerable extent known, and marked on the charts and given in books on "Sailing Directions"; but to these currents have to be added the modifying influence of prevalent winds, and what we want to get at is the resulting average effect. We want to know in what direction an object set floating at any spot will probably be carried at various times of the year in ordinary weather. The surface organisms are such feeble swimmers, if locomotory at all, that any results obtained from small floating bottles may reasonably enough be regarded as holding good for the plankton.

The form of bottle we have chosen is cheap, buoyant, strong, and well corked. It measures 7·5 cm. in length over all, and 1·8 cm. in diameter. Inside it is placed a printed paper requesting the finder to fill in date and locality, in spaces left for the purpose, and post it back to myself. The papers are numbered, and are folded in the bottle in such a way that the distinguishing numbers can be read through the glass, so as to ensure that the bottles are set free in consecutive order. After the bottle has been corked up, the end is immersed a couple of times in melted paraffin, so as to close up the pores in the cork. None of the papers that have been returned show signs of water having got into the bottles.

As to the distribution, I sent off the first few dozen myself from steamers crossing between Liverpool and the Isle of Man, dropping a bottle over every fifteen or twenty minutes between the Bar and Douglas, and also from a steam-trawler while dredging between Port Erin and Ireland. Mr. A. Holt has had a number of bottles distributed for me from his outward-bound steamers on their course between Liverpool and St. George's Channel, and from the Mull of Galloway round to the Mersey. The Lancashire Sea-Fisheries steamer has set free another series along various lines up and down the Lancashire coast, and finally some have been set free at equal intervals of time during the rise and fall of the tide from the Morecambe Bay Light vessel in the northern part of the district, and from the Liverpool North-west Light vessel in the southern part. The distribution has now been going on since the beginning of October, and a very fair proportion (about one out of every three) of the papers have already been returned to me duly filled in and signed. They have come from various parts of the coast of the Irish Sea—Scotland, England, Wales, Isle of Man, and Ireland. Some of the bottles have gone quite a short distance, having evidently been taken straight ashore by the rising tide. Others have been carried an unexpected length—*e.g.* one (No. 35) set free near the Crosby Light vessel off Liverpool at 12.30 p.m. on October 1, was picked up at Saltcoats in Ayrshire on November 7, having travelled a distance of at least 180 miles (probably far more) in 37 days or less; another (H 20), set free near the Skerries, Anglesey, on October 6, was picked up at Ardrossan, Ayrshire, on November 7, having gone at least 150 miles in 31 days.

It would be premature as yet, until many more dozens or hundreds have been distributed and returned, to draw any very definite conclusions. It is only by the evidence of large numbers that the vitiating effect of exceptional circumstances, such as an unusual gale, can be eliminated. However, I may state, as provisional results so far, that nearly fifty per cent. of the bottles found have been carried across to Ireland, and they are chiefly ones that had been set free in the southern part of the district (between Liverpool and Holyhead) and off the Isle of Man. The bottles set free along the Lancashire coast and in Morecambe Bay seem chiefly to have been carried to the south and west—to about Point of Ayre, in North Wales, and Douglas, in Isle of Man. It is apparently only a few that have been carried out of the district through the North Channel. The most interesting point, so far, is that so many of the bottles have been stranded on the Irish coast, although they were sent off for the most part much nearer to the English and Welsh coasts, showing no doubt the influence of the spell of easterly winds in October. W. A. HERDMAN.

The Explosion of Gases in Glass Vessels.

WHEN Prof. Lothar Meyer was visiting Manchester a few years ago (on the occasion of the meeting of the British Association), he surprised me by saying that it was his custom in lecture to explode mixtures of ethylene and other hydrocarbons with oxygen in glass cylinders, some 10 to 12 inches long by $1\frac{1}{2}$ to 2 inches in diameter (if I remember rightly), and that he had never had an accident. I suppose I did not sufficiently conceal my surprise, for he immediately demanded that we should go to the laboratory and repeat the experiment. Not having a mixture of ethylene and oxygen ready, I could not accept the challenge on the spot. The issue was therefore changed. Prof. Lothar Meyer said that he would fire a mixture of hydrogen and oxygen in a thin glass test-tube without breaking it. I confess I was sceptical, until I saw him do it time after time without injury. He argued that if the thin test-tube would withstand the explosion of hydrogen and oxygen, a thick glass cylinder would withstand the more violent explosion of a hydrocarbon. Nevertheless I ventured to warn him against trying the experiment with either acetylene or with cyanogen, the two gases I had found to explode more violently than any others, *especially with a small quantity of oxygen*. Prof. Meyer's recent accident with acetylene and oxygen has led him to warn chemists against the danger of that mixture. I would wish to add to that warning that the danger is equally great, if not greater, with a mixture of cyanogen and oxygen.

Prof. Lothar Meyer asks how we can account for the violence of the explosion of acetylene, when the velocity of its explosion is so little greater than the velocity of explosion of marsh gas and of ethylene, while it is far less than that of hydrogen? It is important to bear in mind that the explosion-wave is not set up at once; when a gaseous mixture is ignited at the open end of a tube the flame starts comparatively slowly. The violence of an explosion in a short tube depends mainly on whether the explosion-wave is set up or not. I think the immunity so long enjoyed by Prof. Meyer's cylinders depends on the fact that the wave was not set up. I have found that pieces of strong combustion tubing, which will stand an hydraulic pressure of twenty-five atmospheres, are broken by the explosion-wave of hydrogen and oxygen. It requires exceptionally strong glass tubes, capable of bearing at least 120 atmospheres, to withstand the shock of the explosion-wave with cyanogen or acetylene. With both these gases it is the incomplete combustion which occurs with the greatest rapidity and violence. According to the hypothesis I have published, viz. that the explosion-wave travels with the velocity of sound in the burning gases, the pressures existing in the explosion-wave of cyanogen and acetylene with their own volume of oxygen are 117 and 105 atmospheres respectively. Quite apart from this hypothesis, the pressures may be calculated from Riemann's equation for the propagation of a wave of constant type, since we know the density of the unburnt gases and the rate of propagation of the wave. According to Riemann's equation the pressure in the cyanogen explosion is 140 atmospheres, and in the acetylene explosion 114. Some experiments I have recently made in conjunction with Mr. J. C. Cain confirm these calculated pressures. When the explosion-wave was propagated through a mixture of equal volumes of cyanogen and oxygen it broke soda-lime tubing of 18 m.m. external diameter and 2·5 m.m. thickness. Pieces of this tubing broke at a mean hydraulic pressure of 70 atmospheres. Green glass tubing of 2·8 mm. thickness withstood the explosion; it broke at a pressure of 140 atmospheres. More exact results were obtained when the gases were diluted with an equal volume of nitrogen:—$C_2N_2 + O_2 + 2N_2 = 2CO + 3N_2$.

Pieces of the tube which were broken by the explosion were broken hydraulically at 63 atmospheres; pieces of the tube which withstood the explosion were broken hydraulically at 84 atmospheres.

Pressures in the Explosion Wave.

Gaseous mixture.	Calculated pressures.		Observed pressures.
	Riemann.	Dixon.	
$C_2N_2 + O_2$	140 At.	117 At.	70 – 140
$C_2N_2 + O_2 + 2N_2$	73·5 At.	57 At.	63 – 84

When oxygen is added to these mixtures the rate of explosion is diminished and the pressure falls. For instance, according to Riemann's equation, the pressures produced in the explosion of acetylene with increasing quantities of oxygen are as follow:—

Gaseous mixture.	Calculated pressure.
$C_2H_2 + O_2$	114 At.
$C_2H_2 + O_3$	98 At.
$C_2H_2 + O_5$	78 At.

In the same way the pressures produced in the explosion of ethylene with different quantities of oxygen may be calculated:—

Gaseous mixture.	Calculated pressure.
$C_2H_4 + O_3$	98 At.
$C_2H_4 + O_4$	91 At.
$C_2H_4 + O_6$	78 At.

The lowest of these pressures is probably sufficient to break the cylinders used by Prof. Lothar Meyer. As Prof. Thorpe says in NATURE, the danger of acetylene lies in the rapidity with which the explosion-wave is initiated, even when the air alone is used as "tamping." Safety lies not in thickening the glass, but in shortening the tubes. H. B. DIXON.

Owens College, December 1.

The Kinetic Theory of Gases.

I HAVE to thank Mr. Culverwell for his reply to my letter on the discussion at Oxford. To quote his own words (in answering Mr. Burbury, p. 105), Mr. Culverwell's letter was "exactly the kind of letter that I hoped to elicit," as I had not been able to recall the exact purport of Prof. Fitzgerald's "onslaught." Although Prof. Boltzmann made no attempt to answer Prof. Fitzgerald's objections in the short space of time available after the other speakers had concluded, he several times mentioned the question to me after the debate as one which had not been hitherto satisfactorily cleared up. In preparing my Report, the question of the spectra of gases came prominently before me, but I purposely refrained from expressing my own opinions on a subject about which so little had been written in a report which was intended to be chiefly a record of work actually done. My frequent allusions to the question of the *uniqueness* of the Boltzmann-Maxwell Law were intended, however, to pave the way, if possible, for an explanation of the discrepancies alluded to by Prof. Fitzgerald, and I should like now to attempt to answer some of his objections.

According to Mr. Culverwell, Prof. Fitzgerald asked why the ether, the solar system, and the whole universe were not subject to the Boltzmann-Maxwell Law? Let us take the solar system first.

The law is obviously inapplicable to a *single* system (as I pointed out in my Report, and hope to prove still more conclusively shortly). In order to apply it, Prof. Fitzgerald would have to take *an infinitely large number of solar systems*, each consisting of similarly constituted planets differing, however, in their motions. What the law states is that, if the coordinates and momenta of the different systems were at any instant distributed according to the Boltzmann-Maxwell distribution (*i.e.* with frequencies proportional to e^{-hE}), they would be so distributed at any subsequent instant. In the absence of mutual action between the various solar systems, this would *not* be the only permanent distribution, nor would there be any tendency to assume such a distribution. If, however, the different solar systems were to collide with or encounter one another *at random* in such a way that transference of energy was liable to take place between any of the coordinates of any one system and any of the coordinates of any other system, the Boltzmann-Maxwell distribution *would* probably be unique, and there would be a tendency to assume such a distribution as the ultimate result of a great number of encounters taking place. Will not Prof. Fitzgerald agree to this?

With regard to the ether, I notice that Mr. Culverwell emphasises Prof. Fitzgerald's contention that the investigations ought to take "ethereal" as well as "molecular" coordinates and momenta into account. But here I agree with Prof. Boltzmann that the *onus probandi* lies with physicists. If they will give us a clear and definite statement as to *what are the coordinates and momenta of the ether*, and *how transference of energy takes place between these and the molecules*, and if they will show that the Boltzmann-Maxwell Law is violated under conditions under which we have proved it to be unique, a "true bill will have been found."

At present all we assert is that if the "ethereal coordinates and momenta" satisfy a determinantal relation similar to that proved on p. 22 of Dr. Watson's new edition, the Boltzmann-Maxwell distribution, *if it ever once existed*, will be permanent *in the absence of disturbing influences*. But the test case in which molecules are regarded as smooth solids symmetrical about an axis (see my Report, § 45, case iii.) affords an instance in which partition of energy does not take place between *all* the coordinates of a system, the angular velocity of each molecule about its axis of symmetry being constant and unaffected by collisions, and therefore independent of the Boltzmann-Maxwell Law. And why should not a similar explanation be applicable to the ether? At any rate, this hypothesis is supported by the views advanced by Prof. Oliver Lodge at the Nottingham meeting of the British Association ("Nottingham Report," p. 688). G. H. BRYAN.

Cambridge, November 30.

IT appears to me that the difficulty raised by recent critics against Maxwell's law of partition of energy in the theory of gases, and Boltzmann's minimum theorem relating thereto, by consideration of the effect of a complete reversal of the motions, is capable of direct explanation; and that whatever weak points the theory may have, they are not in that direction. Indeed, if that were not so, the criticism would apply equally against the Second Law of Thermodynamics.

The theorem in question is that there exists a positive function belonging to a group of molecules, which as they settle themselves into a steady state maintains—on the average derived from a great number of configurations—a steady downward trend; that the Maxwell-Boltzmann steady state is that one for which this function has finally attained its minimum, and is thus the unique steady state; it still being borne in mind that this is only a proposition of averages derived from a great variety of instances in which nothing is conserved in encounters except the energy, and that exceptional cases may exist, comparatively very few in number, in which the trend is, at any rate temporarily, the other way.

Such an exceptional case is in fact the very striking one, pointed out by Maxwell and Helmholtz, in which the motions of the system are all at some stage precisely reversed, so that it retraces its previous history backwards, and the trend of the reversed system is therefore in the opposite direction to the one which would lead towards the steady state. Now it has been assumed, at first sight plausibly, that there are just as many cases of this reversed motion as there are of the direct motion; and if that were so, it would undoubtedly go hard with the distribution theorem. But a fallacy underlies such an assumption, as indeed the other accepted proofs of simple cases of the distribution theorem would lead us to expect. Consider an arbitrary distribution of velocity and configuration of the system to begin with; and let it settle down for a time towards the final state, whatever that may be. Suppose at the end of that time that its velocities are all reversed; the system will retrace its course up to the initial state, but when it has got there, it will presumably go on settling down towards the final state by another route, because there is no longer any reason for exceptional behaviour. Thus there will be only a temporary aberration in the course of the reversed system; and further, if the original progress towards a steady state was at all rapid, this aberration will be sensible only for a brief time, the remainder of the history of the reversed motion corresponding nearly to the steady state. It is true that if the whole universe were thus reversed, the aberration would be permanent; but then the whole universe is a permanently dissipative system, and there is no question of a steady state being attained by it in measurable time. For a finite system, like a mass of gas imagined as bounded by a rigid envelope, the case would be different.

Thus even if these reversed states amounted to half the possible states, there would still be a preponderating, though not immense, probability in favour of a final settling down. But are these reversed states half the total number? The characteristic of such a state is that it is derived from an entirely fortuitous initial distribution by a process of change which is in the direction of the final steady state, whatever that may be, and much in that direction if the time concerned be considerable. It seems then that the number of configurations which can retrace their history for a sensible time is very much more limited than the total number of possible configurations, and that they are simply the exceptions which do not disprove the rule. For a theorem of average, derived from a very great number of instances, is of course not invalidated by picking out a comparatively small number of instances which depart widely from the average. J. LARMOR.

Cambridge, December 4.

Peculiarities of Psychical Research.

MR. H. G. WELLS disposes very aptly of most of the claims set up by Mr. Podmore and his colleagues to be real scientific investigators. But, I think, he rather disguises the significance of the card-drawing experiments to which he refers. The experiments of M. Richet and those of the S.P.R. belong to two very different categories. In the former case, 789 correct guesses were made in 2927 trials, or a deviation from the most probable result of 57 or 58; this is about 2·4 times the standard deviation, or the odds against a deviation *in excess* of this amount are only about 100 to 1, or odds of only about 50 to 1 of a deviation of this magnitude either way.

On the other hand, in the S.P.R. trials we have a deviation from the most probable of 347, about six times the standard deviation. That is to say, the odds against such a result are in round numbers about 2,000,000,000 to 3! Now, this is of a totally different order to that given by M. Richet's numbers. I have obtained odds as great as 100 to 1 against the results of very carefully conducted lottery experiments. There is in reality nothing significant about such odds. But the odds against the S.P.R. experiments are almost equal to the odds against the Monte Carlo roulette returns! The experiments are significant, very significant—not to my mind, however, of telepathy, but of the want of scientific acumen in the psychical researchers. The interesting point as to whether an abnormal distribution was also in the cards turned up as well as in the percipient, does not appear to have been recorded. Mr. Wells has, however, passed over the difference between the two cases, and given, I fear, the psychical researchers the chance of a little self-glorification on their due appreciation of the significant.

University College, December 8. KARL PEARSON.

Chronometer Trials.

THE Mersey Docks and Harbour Board have, by an Order dated November 29, 1894, modified the regulations under which they are prepared to issue certificates to those who deposit chronometers and other scientific apparatus at their Observatory for test and examination. Under the new regulations, instrument-makers can re-submit their apparatus within a twelvemonth of first deposit, without any additional fee. In the case of chronometer-makers this concession will probably be welcomed for the following reasons. Hitherto, the certificates granted have simply been regarded as a protection to the public, and the makers have had to apply their own tests to ensure accurate performance before submitting them to independent examination. But it will now be possible for makers to spare, in some degree, their own rigorous control, since the certificate granted will show the direction in which correction must be made, and a second certificate will be granted without fee to the improved instrument. If no alteration be needed, the time required for the additional trial is of course saved. Another modification, which will be appreciated by those who seek certificates for watches, is that affecting the condition under which these certificates are granted. The alteration will be best shown by an example. Suppose a watch to have a normal rate in the first position of trial of nine seconds a day, and under the various tests to which it is submitted the rate increase more than a second daily. Such a watch or chronometer, under the old regulations, would be refused an "A" certificate because the daily rate increased to more than ten seconds from mean time. But the watch might evidently be superior to one with a normal rate of two seconds, and which varied some five or six seconds in the various stages of its trial. The alteration in the regulations sanctioned by the Board will now permit the variations to be reckoned from the normal rate, and not from mean times. WILLIAM E. PLUMMER.

Liverpool Observatory, December 10.

Indo-Malayan Spiders.

IN your issue of November 29, Mr. R. I. Pocock, reviewing Mr. and Mrs. Workman's book on "Malaysian Spiders," states: "But the pine-apple is a native of South America, and has only of *late* years been introduced into Singapore; &c." Now, twenty years ago it was as common at Singapore as any other fruit, more so than many indigenous ones. How long before it may have been introduced I am unable to say, but that also should surely be stated "Before such a conclusion, however, can be looked upon as an established fact." I quite grant that in all probability the plant and spider were introduced simultaneously.

New Club, Grafton Street, W. B. A. MUIRHEAD.

Death-feigning in Snakes.

IN NATURE of November 29, p. 107, L. C. Jones asks whether death-feigning is, among snakes, confined to *Heterodon platyrrhinus*.

A writer in the *American Naturalist*, November 1894, pp. 966–8, tells almost precisely the same story of the "Moccasin" snake (*Ancistrodon*) and of "a black or blowing viper."

He also finds "letisimulation" in the toad, and in certain arthropods, worms, and protozoa.

December 1. GERARD W. BUTLER.

The alleged Absoluteness of Motions of Rotation.

PROF. GREENHILL'S remarks on my letter on this subject (NATURE, November 29), admitting that he is unconverted, and throwing out a suggestion that further arguments or explanations are desirable, appear to open a wider question than can be effectively dealt with in the limits of an ordinary letter. I propose therefore to deal with the subject in a special article to be written shortly. A. E. H. LOVE.

St. John's College, Cambridge, December 3.

Gravitation.

MAY I ask Dr. Joly whether Newton himself did not point out that a graduated tension excited by matter in a continuous inextensible medium, of an intensity proportional to the mass and the inverse distance, would account for gravitation; and whether he did not refrain from further elaborating this idea because there seemed at that time no adequate way of explaining the existence of such a tension? OLIVER J. LODGE.

"Outlines of Quaternions."

MAY I make a short explanation on one or two points on which my reviewer (NATURE, November 22) does not appear to have understood me?

(1) I mentioned Prof. Hardy and Dr. Odstrčil's names in one or two places, because I quoted their language verbally. I found it was better than any language I could devise.

(2) The extraordinary oversight on p. 76 would never have seen the light had I had either good health, or the assistance of a friend, in correcting the proofs of a MS. which was written at odds and ends of time, at places as widely separated as Norway, Gibraltar, and India.

(3) My reviewer says eq. 8 of p. 40—$i = \sqrt{-1}$—"plays sad havoc with one's very definitions." Having defined i as a right versor on p. 37, and explained on p. 39 that i^2 means ii, I deduced in the usual manner the eq. —$i^2 = -1$, or—

$$ii = i^2 = -1 = \sqrt{-1}\sqrt{-1}.$$

Hence I concluded that $i = \sqrt{-1}$; and I fail to see how I have played havoc with my definitions in doing so. Had I begun by explaining that Hamilton built up his system by treating $\sqrt{-1}$ as a right versor perpendicular to the line it operates on, I might have been open to criticism; but I did not do so. I took another course, which may not have been the best one; but that is a different thing from violating one's own definitions. H. W. L. HIME.

24 Haymarket, S.W., November 26.

[A pointed reference to a scientific writer usually implies one of three things—that the writer is an authority on the particular subject under discussion, or has made a noted discovery in connection with it, or has been guilty of a serious blunder. Dr. Odstrčil's corollary hardly comes under the second category, and Prof. Hardy's statement differs in no essential word from Hamilton's own language in the "Lectures" (p. 83).

Equation 8 (p. 40, in "The Outlines of Quaternions") asserts the equality of $i, j, k, -i, -j, -k$, and as these symbols are by definition all different, the said equation is inconsistent with the definitions. To speak of $\sqrt{-1}$ as an indeterminate right versor, that is, an operator which rotates any vector through a right angle about an indeterminate axis—a most difficult operation for the mind even to imagine—may be permitted as a figure of speech; but to equate this backboneless thing to a real unit vector or right versor with all its powers of action, is making a serious demand upon the credulity of the student. After *defining* i, j, k as symbols involving both axis and angle, what right or reason has Colonel Hime thus arbitrarily to annihilate the axis? Is it not playing havoc with the very props of the calculus?—THE REVIEWER.]

THE WARBLE FLY.[1]

IT is only within comparatively recent years that much attention has been paid to the insect pests of the farm and garden. It is true that when these assume unusually devastating proportions, especially when they make their appearance suddenly, as in the case of locust-swarms, the attention of whole nations is called to them for the moment; but the loss caused by less obtrusive creatures may proceed unchecked and almost unsuspected for years, without attracting the notice even of those who suffer from it most. But there are now many entomologists, among whom Miss Ormerod deserves special notice in England, and Prof. Riley in America, who have been working zealously for years to diminish the loss and injury caused by injurious insects; and the pamphlet before us, with its clear descriptions and statistics, and excellent illustrations, conveys a mass of information, in a very handy form, which certainly deserves the most serious attention of all who are interested in the cattle and leather trades, whether as graziers, butchers, or tanners.

The total loss caused by the warble fly in the United Kingdom alone is estimated at something like £8,000,000 per annum; an enormous amount, but which the facts given in Miss Ormerod's pamphlet fully appear to bear out. When hides are sometimes so deteriorated that the loss on each may be as much as from twenty-five to thirty shillings, to say nothing of hides rendered utterly worthless; cattle killed, or the best parts of the carcase destroyed, and diminished yield of milk, the importance of the matter becomes very apparent. And beyond this, there remains a very serious question which Miss Ormerod has not touched upon at all: how far the milk of badly-infested cows, or the apparently sound portions of a carcase, even when all the obviously diseased part has been conscientiously removed, may be liable to cause disease in man—disease, possibly, of a nature the origin of which is at present absolutely unknown and unsuspected by medical men. And yet we remember once to have met with the statement that the best hides generally contained warbles. This, however, if true in any sense, could only mean that the fly attacks the strongest and healthiest animals in preference to weaker ones, thereby of course increasing the mischief produced by its attacks.

Although the insect is so abundant that as many as 500 maggots have been found in a single hide, yet the fly is rarely seen. When the cattle are attacked by it, they gallop wildly about, with their tails in the air, and seek the shelter of trees or sheds, or rush into the water; and in any of these situations, the fly does not appear to follow them. Cattle will act in the same manner when attacked by true gad-flies, one of the largest British species of which, *Tabanus bovinus*, is likewise noticed and figured by Miss Ormerod in her pamphlet. The gad-flies, however, simply pierce the skin of the cattle, and suck their blood, but inflict no permanent injury; and their larvæ are subterranean, and not epizootic.

According to the observations of Prof. Riley in America, the egg of the warble fly is deposited on, and not under, the skin. In the earliest stage of the maggot, which Miss Ormerod has herself observed, it is a small blood-red worm-like creature, scarcely visible to the naked eye, embedded in a slight swelling, composed of blood-red tissue, through which a fine channel, no wider than a hair, passes up to the surface of the skin (Fig. 1). In the very young stage, the maggot, which always rests with its head at the bottom of the sore, and the breathing apparatus, which is at the opposite extremity of the body, directed towards the opening which communicates with the external air, is provided with two forks or diggers, probably used for piercing through the substance of the hide. In this stage, too, the maggots are capable of inflating themselves with fluid which they have apparently no means of discharging, and become so hard that they can scarcely be compressed with the fingers, thus forming living and growing plugs, which act the part of setons, and which cannot be pressed back out of the wound, more especially as they are furnished with short bands of prickles along a portion of the back. Having penetrated the hide, the

[1] "Observations on Warble Fly or Ox Bot Fly (*Hypoderma bovis*, De Geer)." By Eleanor A. Ormerod, F.R.Met.Soc., &c. (London: Simpkin, Marshall, Hamilton, Kent, and Co., Ltd., 1894.)

maggot rests in the sore, and presently assumes a more pear-shaped form.

When about one-third grown, a great change takes place in the structure of the creature, which, while it was forcing its passage, was "little more than a bag of fluid, with a large proportion of the space *occupied by breathing-tubes*." At this stage, however, "the hard tips necessary, or at least serviceable for forcing a passage up the hide, are no longer needed, and they are exchanged for a broad form of spiracle, and the internal organs become suited to provide material for the development of the fly, which will presently form in the dry husk of the maggot, which serves as the chrysalis-case."

The further development of the maggot is so well known that we scarcely need trace its course until it reaches its final shape of a hairy two-winged fly, not very unlike a small humble-bee in general appearance, nor need we go into the elaborate accounts of the enormous loss which is frequently caused by it to all persons interested in living or dead cattle. The fly

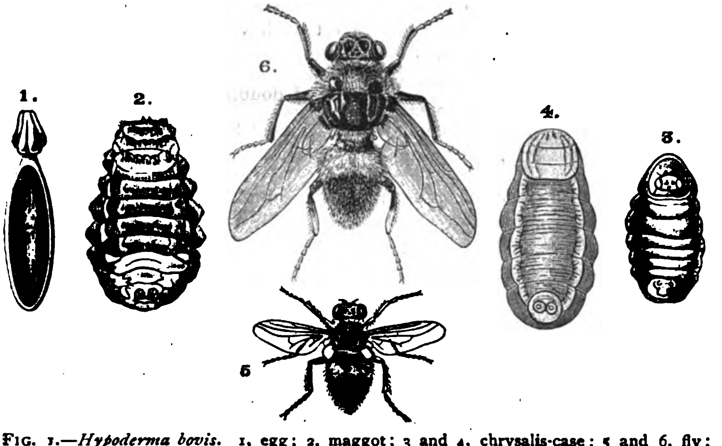

FIG. 1.—*Hypoderma bovis.* 1, egg; 2, maggot; 3 and 4, chrysalis-case; 5 and 6, fly; 3 and 5 natural size, after Bruey Clark; the other figures, after Brauer, and all magnified.

appears to be found in most parts of the world, but is a much greater pest in some countries than in others; and it is worthy of notice that, while goats appear to suffer from the warble as much or more than cattle, horses seem never to be attacked by it.

Miss Ormerod, however, gives several easy, harmless, and efficacious methods by which the mischief may be abated or removed; and the fly appears to be sluggish, and not to stray far from where it lived as a maggot, for after a few years' careful destruction of the maggots, the pest seems to disappear, without the farm being liable to fresh incursions from surrounding farms where similar precautions have not been taken to exterminate the maggots. Miss Ormerod has evidently done her best to show the farmers how they may best exterminate the pest; and if they do not avail themselves of the information which she has been at so much trouble to collect and to disseminate, it will not be her fault. The accompanying illustration is from her useful pamphlet.

W. F. KIRBY.

FERDINAND DE LESSEPS.

THE death of M. de Lesseps, on Friday last, removes from the world one of its more prominent men. To say that it was his indefatigable energy which brought to a successful termination the scheme to pierce the Isthmus of Suez, is but to repeat what is known to every schoolboy. With the affairs that during the last two years have obscured his fame to the political eye we have nothing to do. The work which earned for him the title of "Le Grand Français" is sufficient to command the admiration of every man of science. The appreciative obituary notice in the *Times*, running into nearly four columns, deals largely with de Lesseps' diplomatic career, but this does not concern us. We are indebted to the notice, however, for some of the following particulars of interest to our readers.

Ferdinand de Lesseps was born at Versailles, November 19, 1805. His early public life was spent in the diplomatic service, for which he manifested the same predilections as his ancestors. But so far back as 1841, the project for cutting through the Isthmus of Suez had occurred to him. It was not until 1854, however, that he first revealed the scheme that will be most lastingly associated with his name. Two years later, Said Pasha, the Viceroy of Egypt, granted him a formal letter of concession. In the same year de Lesseps published a clear and definite exposition of his views in his pamphlet "Percement de l'Isthme de Suez. Exposé et documents officiels." Many eminent engineers questioned the practicability of the scheme; nevertheless a capital of two millions of francs was subscribed, and in 1859 the works were commenced.

Difficulties and disputes of a most serious character cropped up from time to time, but they were overcome, with the result that a canal, having sufficient water to admit of the passage of steamboats, was opened on August 15, 1865. The channel was widened and deepened by special machinery, and in March, 1867, small ships were able to make use of the Canal. The waters of the Mediterranean mingled with those of the Red Sea in the Bitter Lakes on August 15, 1869, and the event was commemorated by grand *fêtes* at Suez. On November 20 following, the Canal was formally opened at Port Said amid a series of brilliant festivities. The Canal is about 100 miles long, with a bottom width of upwards of 200 feet, and a depth of 28 or 29 feet.

Honours poured in upon M. de Lesseps after the successful opening of the Canal. In February, 1870, the Geographical Society of Paris awarded him the Empress's new prize of 10,000 francs. He gave it as a contribution to the Society's projected expedition to Equatorial Africa. He was appointed to the rank of Grand Cross of the Legion of Honour, and received the cordon of the Italian Order of St. Maurice. The honorary freedom of the City of London was presented to him, and Queen Victoria created him an honorary Knight Grand Commander of the Order of the Star of India. In July, 1873, the Paris Academy of Sciences elected M. de Lesseps a member, in the place of the late M. de Verneuil. In 1875 he published his "Lettres, Journal, et Documents pour servir à l'Histoire du Canal de Suez." For this work the French Academy awarded to him the Marcelin Guérin prize of 5000 francs. In June, 1881, he was elected President of the French Geographical Society, in the place of Admiral de la Roncière-le-Noury. The Broad Riband of the Persian Order of the Lion and the Sun was presented to him in 1883.

M. de Lesseps promoted the project of the Corinth Canal, and made a journey in Algeria and Tunis to study the scheme of Commandant Rondaire for the creation of an inland sea in Africa—a scheme of which he formed a favourable opinion. Gradually, however, he became wholly absorbed in the undertaking which was to prove his ruin—the Panama Canal. All the world knows how this ended. After the humiliating drama had been played out at the beginning of last year, the central figure sunk into a state of stupor, and in this condition—almost oblivious of everything that went on around him—he remained until he passed into the silence of death.

But let us forget these events. However dark they may seem to be, they cannot hide from us the wonderful applications of science we owe to Lesseps.

We learn from the *Times* that Mdme. de Lesseps has received many messages of condolence. The Emperor of Germany telegraphed to her, "All intellectual and scientific people mourn over the tomb of one of the greatest minds and of a genius which embraced the universe." Lord Dufferin has conveyed the sincere grief of the Prince of Wales, as also the sympathy of Lord Kimberley. It is understood that a committee of the Suez Canal Board is to propose to the company that a statue be erected to M. de Lesseps at the expense of the company, and that the city of Paris is to be asked to grant a site in one of the public squares.

These expressions show the high regard in which de Lesseps was held. A still more striking testimony is afforded by the fact that the Paris Academy of Sciences adjourned on Monday in sign of mourning, when the president, M. Lœwy, is reported to have said: "Many storms had latterly broken over the head of the illustrious veteran. It is, perhaps, not to be too much regretted that his declining strength had for several years made him almost a stranger to the melancholy affairs of this world. His name will for ever be linked with a grand work, the success of which is due entirely to his glorious efforts, and will be a memorable date in the history of civilisation."

Scientific posterity will remember the Academy's act of respect to de Lesseps, and M. Lœwy's words of tribute to his colleague's memory.

NOTES.

WE are glad to see the report that M. Pasteur, who has been poorly for some little time, is improving in health.

PROF. G. LEWITZKY, the Director of Charcow Observatory, has been appointed Director of Dorpat Observatory, in succession to the late Prof. L. Schwarz. Dr. L. Struve goes to fill Prof. Lewitzky's place at Charcow.

THE Academy of Sciences of Berlin has granted a subsidy of 1200 marks to Dr. P. Kuckuck, to aid him in the investigation of the alga-flora of Heligoland.

WE learn from the *Botanisches Centralblatt*, that Herr W. Siehe, of Berlin, has undertaken a botanical exploration of the almost unknown region of Cilicia Trachæa.

CONSIDERABLE changes have recently been made in the scientific department of Smith College, U.S.A. The botanical department has been reorganised, and Dr. W. F. Ganong appointed professor. Miss Grace D. Chester, formerly instructor in botany, has been appointed instructor in cryptogamic botany.

OUR correspondent at Cambridge has sent us the following notes:—The Council of the Senate have appointed Dr. R. D. Roberts to be a governor of the Royal Holloway College, Egham. Dr. H. H. Tooth, of St. John's College, has been appointed an additional examiner in medicine. The Walsingham Medal for biological research has been awarded to H. Burkill, assistant curator of the Herbarium. The following awards for Natural Science have been made at St. John's College: G. S. West, Royal College of Science, London, Foundation Scholarship of £80 a year; E. F. Hudson, Dulwich College, and T. F. R. McDonnell, St. Paul's School, Minor Scholarships of £50 a year; A. C. Ingram, Felsted School, Exhibition of £30.

A SOCIÉTÉ des Amis des Explorateurs français has recently been formed at Paris. Its object is to collect and administer funds for the purpose of aiding travellers, particularly in their return, and to contribute to the progress of geography by the publication of the results of explorations, and other contributions to geographical science. The Society is in connection with the Paris Geographical Society.

WE thought it would come. The anti-vaccinationists, anti-vivisectionists, and kindred souls have, if only for the sake of consistency, protested against the new treatment for diphtheria. At the ordinary fortnightly meeting of the Metropolitan Asylums Board, on Saturday last, a deputation, headed by Lord Coleridge, waited upon the Board to present a memorial against experiments being carried out in the hospitals in the Metropolitan Asylums district in the use of the anti-toxin cure for diphtheria. The Royal College of Physicians had offered to supply serum for the treatment of diphtheric patients in the Board's hospitals, and the General Purposes Committee advised the acceptance of it, but the deputation wished to stop the action altogether. By arguments that have been used over and over again, it was urged that the experiments led to injurious effects, and were of doubtful utility. Therefore, the deputation submitted, "public money ought not to be devoted to experiments in physiology." The Board, however, thought differently, for the report of the Committee was adopted.

PROF. W. C. MCINTOSH writes on the artificial hatching of marine food-fishes in *Science Progress* for December. In the course of his article, he pleads for increased funds to carry on experiments on a larger scale than is at present possible at Dunbar. The sum of £3000 per annum is granted to the Scottish Fishery Board for scientific investigations, but really only £1800 a year is available for research. "This income has to bear the salaries of the staff, experiments in fish-, lobster-, and mussel culture, the cost of apparatus, the marine laboratory at St. Andrews, the hatchery for marine fishes, with its small laboratory at Dunbar, and the carrying out of other scientific fishery work." Leaving England out of consideration, compare this with what is done on the other side of the Atlantic. "The United States spends annually £70,000 on fish-culture and scientific investigations, and employs two large steamers and a sailing vessel exclusively for the work. Besides this large sum, the Fish Commissioners of the various States also disburse considerably on the development of their fisheries. Canada, again, expends £100,000 yearly on her fisheries, of which a sum of about £10,000 is devoted to fish culture."

IT was pointed out by Lord Rayleigh in these columns in 1883 (vol. 27, p. 535), that whenever a bird pursues its course for some time without moving its wings, we must conclude either (1) that the course is not horizontal, (2) that the wind is not horizontal, or (3) that the wind is not uniform. Prof. S. P. Langley's recently published memoir on the internal work of the wind shows that the condition represented by the third cause, which Lord Rayleigh believed must sometimes operate, always exists. The investigations described in the memoir distinctly prove that the wind is never a homogeneous current, but consists of a continued series of rapid pulsations varying indefinitely in amplitude and period. These pulsations undoubtedly help a bird to maintain its flight without working its wings or expending energy. This may be accomplished by a succession of ascents and descents; the ascents being made during the wind-gusts, and the descents during the lulls. Prof. George E. Curtis, of Washington, has lately investigated mathematically whether the third case of Lord Rayleigh's analysis is the one actually employed by a bird in soaring; that is to say, he has tested whether the pulsations of the wind, in addition to being qualitatively applicable, are also quantitatively sufficient to produce the result. (*Annals of Mathematics*, vol. viii. No. 6.) With this application in view, he has determined the course in the air of a free heavy plane subjected to definite wind pulsations. For a period of action of ten seconds, the following result was obtained "without any internal source of energy, during the 10 seconds of alternate calm and wind, the plane has in the first 2·75 seconds made a descent of 36 feet, and in the remaining 7·25 seconds has risen 46·9 feet, travelling at the same time horizontally a distance of 251 feet, of which 154 feet is made against the wind. In addition, the relative velocity of the plane and wind (58·9 feet per second) at the end of this period is sufficient, if the wind continue with the same velocity, to yield a considerable further ascent before the vertical component of pressure is reduced to such an extent that it no longer exceeds the weight of the plane under the constant angle of inclination." Though the conditions of the problem solved by Prof. Curtis are seldom met with in nature, the results he has obtained have a very important bearing upon mechanical flight.

A NUMBER of papers of considerable value are published in the *Mittheilungen der Prahistorischen Commission der Kais. Akademie der Wissenschaften*. (Bd. 1, No 3. Wien, 1893). J. Szombathy describes the ceramics discovered by him in a tumulus at Langenlebarn, in Lower Austria. He points out that double and multiple vessels were common in the finds of the bronze period and first iron age of the eastern Mediterranean countries, especially in Cyprus and Troas, somewhat rarer at a later time in the graves of the first Italian iron age, and still more rare in the later graves of the Hallstatt period of the Austrian Alps and of Central Europe. The doubling arose from the gradual increase in diameter of the lower portion of the long cylindrical neck of an earlier type of vessel. Dr. M. Hoernes gives a study of the forms of various prehistoric objects which he has observed in the museums of North-east Italy. Amongst other objects he refers to bronze and iron knives in the museum at Padua. The resemblances in the handles and ornamentation of certain clay vessels leads him to the conclusion that the culture of the bronze age of North-eastern Italy extended to the East, and included Bosnia-Herzegovina and Istria; but from this he does not deduce an ethnical relationship. In the bronze period of Eastern Upper Italy not only were pile-dwellings inhabited, but mounds as well, as in Istria and Bosnia-Herzegovina. Even if related pile-structures are not to be found in the north-west of the Balkan Peninsula, the difference in the mode of life is counterbalanced by other considerations. The evolution of the Italians and the Illyrians later diverged in the historically well-known way. He would add the Ligurian people as belonging to the same culture group of that age; this culture-unity separated these people from other peoples living further north and south of this zone. Dr. Hoernes also describes some triangular and other ornaments, human and animal forms, especially those with associated birds, as well as bronze and iron fire-dogs. Prof. R. Trampler writes on the oldest graves in the Brünnen Valley district; and F. Heger, on finds from prehistoric and Roman times in Lower Austria. The author of this well-illustrated paper states that there was a pure bronze age in the district of Upper and Lower Austria, which had points of relationship with the Western finds, and especially with those in the North and East.

A CURIOUS formation is illustrated in the first annual report of the Iowa Geological Survey, published a few months ago. Good exposures of limestone rocks are found all along the Mississippi from Keokuk to Burlington, in south-eastern Iowa. The limestone often stands out in overhanging cliffs over the softer shale beds beneath, and gives the appearance of a cascade, as shown in the accompanying illustration, which is reduced from a plate in the report. The Survey was only established

in 1892, but the report shows that a large amount of useful information, of great economic interest to the people of the State, has already been collected.

THE volume referred to in the foregoing note showed us that the publications of the Iowa Geological Survey were to be of a high character. The second volume, which reached us a few days ago, goes to confirm this view. It is a description of the coal deposits of Iowa, by Dr. C. R. Keyes, and is a model of what a general report should be. With text running into more than five hundred quarto pages, eighteen full-page plates of a high quality, representing interesting formations in connection with the coal-measures, and over two hundred figures in the text, the volume is an attractive handbook for the coal-miners of Iowa. It is not a detailed account of the geological features of the coal districts—that will follow when sufficient facts have been accumulated; it is rather a preliminary report, somewhat general in character, but sufficient to supply temporarily the demand for information pertaining to the coal deposits of the State. Separate volumes will be devoted to practical mining in Iowa, and to a description of the uses and properties of Iowa coals. We offer our congratulations to Dr. Keyes and the geological corps with which he is associated. May their intentions with regard to future work be satisfactorily realised.

IN the current number of the *Zoologischer Anzeiger* (No. 462), Dr. Arnold Graf records some novel observations made by him in the course of some experiments on the effects of compression on the segmentation of the egg of the sea-urchin *Arbacia*. Driesch has already shown that compression of the segmenting egg between slide and cover-slip leads to the formation of a flat plate of blastomeres, and Dr. Graf's observations coincide completely with those of Driesch up to the 32-cell stage. At this point the author determined to remove the pressure exerted by the cover-slip, and to notice the effect produced on the egg by this reversion to normal conditions. To his astonishment he found that, after removing the pressure (by gradually adding a surplus of water between slide and cover-slip) the various blastomeres began to fuse together again. In this way a plate of 15 cells was produced, each cell containing two and, in a few cases, three nuclei. Shortly afterwards the separate nuclei in each cell reunited. The last transformation observed by the author was the conversion of the plate into a 12-cell stage, consisting of eight macromeres and eight micromeres. The results of the experiment are full of interest, and well worthy of renewed trial. The author is certain that the fusion of the blastomeres took place quite regularly: the two or three daughter-cells of one mother-cell reunited to form the single uni-nucleated equivalent of the mother-cell again.

CERTAIN obscure phenomena connected with the mingling of two masses of liquid are dealt with by Herr E. Kaiser in the current number of *Wiedemann's Annalen*. Two soap-bubbles or two jets of water when brought into immediate juxtaposition will not always mingle at once, and sometimes they will not do so at all. Impurities in the water or soap solution will encourage fusion, and so will a difference of potential. Whether the influence of the latter may be explained on the supposition of sparks breaking down the intervening layer of air, is a question which has been answered in the affirmative. But Herr Kaiser's experiments tend to show that in reality the difference of potential simply increases the pressure on the intervening air, and forces it out at the sides, thus diminishing the distance between the two surfaces down to the radius of molecular action. He suspended a circular film of Terquem's sugar-soap solution in a wire ring by a delicate spring balance, and brought a bubble to bear against it from below. The film and bubble were placed in electric connection through their supports, and differences of potential due to 1, 2, 3 and more Daniells were subsequently introduced. With the films investigated, the time necessary for fusion was about 3·2 seconds with no difference of potential, 1·4 seconds with one Daniell, and 0·4 with two. With more Daniells fusion took place instantly, and the films burst in most cases. The pressure was 1·016 gr. The displacement of air from between the films was studied by the aid of the Newton's rings formed between them. The rings widened out, rapidly at first, then more slowly, and the mingling was heralded by the appearance of the grey-blue of the first order. A difference of potential simply accelerated this process.

IT has been said by someone, that a whole set of meteorological predictions may be disturbed by a cowboy carelessly throwing down a burning match upon a prairie. The match starts a prairie fire which causes changes extending throughout the atmosphere, and so an accident may upset the most carefully prepared forecast. This is, of course, a far-fetched case, but it is worth while knowing what effects great forest fires have upon the atmosphere. To this end Prof. Cleveland Abbe, in the *Monthly Weather Review*, determines some of the meteorological results of the extensive forest fires in the United States during July and August of this year. It appears that, with regard to their influence upon atmospheric moisture, the experience of the past summer is sufficient to show that forest fires are not necessarily followed by rain, and are not a practical method of inducing rain in dry seasons. Comparing the normal maximum effect of solar heat with the computation of the effect of burning forest, Prof. Abbe finds that, in the locality where it occurs, a forest fire can heat its atmosphere more than the hottest sun of June, in the ratio of 10,000 to 750. Fortunately, however, the general influence of the forest fire upon the whole atmosphere is much smaller than that of the sun, because the fire is of small extent, while the sun affects the whole earth. The actual area covered by the forest fires of August in Minnesota, Wisconsin, and Michigan did not exceed five thousand square miles, whereas the area covered by the smoke, and, therefore, hot air, from these fires before the heat was all lost by radiation, was not less than one million square miles. A comparison of the solar effect over this large area and the more intense forest fire effect over the small area, shows that the former is fifteen times that of the latter. Prof. Abbe's calculations thus afford no foundation for the belief that forest fires have important meteorological sequelæ. The story of the connection between careless cowboys and atmospheric circulation is, therefore, no longer worth telling.

THE current number of *L'Elettricista* contains a description of a new method for measuring small resistances, due to Dr. Pasqualini. This method, which requires no special apparatus that cannot be easily set up in the laboratory, consists in having a coil, composed of a few turns of wire, wound double, so that there are two similar circuits. This double coil is fixed to the case of an ordinary galvanometer, so as to act on the needle. The main current sent through the resistance to be measured passes through one of the circuits of this auxiliary coil. A shunt circuit to the resistance is formed by the second circuit of the coil, the galvanometer, and a resistance-box. The connections are so arranged that the main current and the shunt current in the galvanometer coils tend to turn the needle in opposite directions. The resistance of the shunt circuit is varied till the galvanometer deflection is zero. Suppose K is the galvanometer constant, while K_1 is the constant which expresses the effect of either of the circuits in the auxiliary coils on the needle, and if I and i are the total main current and the fraction which passes through the shunt circuit respectively. Then $K i = K_1 I - K_1 i$, or if R is the resistance of the shunt circuit, the resistance to be measured $= \frac{K_1}{K}R$. The value of the constant $\frac{K_1}{K}$ can be obtained by performing the experiment on a known resistance. With an auxiliary coil consisting of two similar circuits containing four turns each, and a Wiedemann galvanometer of 8 ohms resistance, the author finds he can measure a resistance of ·0002 ohms within $\frac{4}{1000}$ I, using a standard ohm to determine the constant $\frac{K_1}{K}$.

IN a paper communicated to the *Physical Review*, Mr. S. H. Brackett gives an account of some experiments he has made on the magnetic properties of iridium. The samples used contained 98 per cent iridium, with some platinum, and a trace of phosphorus, but no iron. A bar of the metal 13·3 m.m. long, 3·2 m.m. wide, and 0·9 m.m. thick, when brought into the field of an electromagnet, set itself at right angles to the lines of force, and became permanently magnetised in a transverse direction, and when suspended, freely set itself E. and W. The permeability of a larger bar was tested, and was found to be unity; and although the specimen was sharply struck while in the magnetising coil, no induced magnetisation was produced.

A NEW illustrated descriptive price list of electric and magnetic apparatus, for use in colleges and scientific institutions, has been issued by Messrs. King, Mendham, and Co., Bristol.

WE have received a *Jahrbuch* containing the results of meteorological observations made at the observatory of the

Magdeburgischen Zeitung during 1893. The volume is edited by Herr A. W. Grützmacher, and is in its thirteenth year.

THE *Bulletins* of the Michigan State Agricultural College Experiment Station, for October, contain an exhaustive paper on the insects which attack clover, by Mr. G. C. Davis, and one on rape as a forage-plant, by Mr. C. D. Smith and Mr. F. B. Mumford.

THE eighth part of "The Natural History of Plants" has been published by Messrs. Blackie and Son. It deals with the genesis of plant-offspring, one section being devoted to asexual reproduction, while the other refers to reproduction by means of fruits.

MM. J. B. BAILLIÈRE ET FILS, of Paris, following other firms of booksellers and publishers, have commenced the issue of a monthly list of new books, under the title *Bibliographie des sciences naturelles.* The list for November comprises the titles and prices of important works on protozoa, sponges, cœlenterata, echinoderms, &c.

THE *Transactions* of the Academy of Science of St. Louis, U.S.A., include a paper on *Sclerotinia Libertiana*, a fungus parasite of the sunflower, by Prof. L. H. Pammel, to which is appended a bibliography of the fungus diseases of roots, covering thirty-seven pages; also a further instalment of Mr. C. Robertson's observations on the relationship between flowers and insects in the process of pollination, the present paper treating of American species of *Rosaceæ* and *Compositæ*.

A VOLUME containing a number of important papers and reports relating to the gold fields of New Zealand has just reached this country. The mining industry has formed a large factor in the advancement of the colony, and the statement issued by the Government shows the direction in which further developments should be made. The volume comprises reports on the gold fields and coal mines, geological reports on the older quartz-drifts in Central Otago, and a report on deep quartz-mining in New Zealand.

MR. EDWARD STANFORD has acted wisely in reissuing Dr. A. R. Wallace's standard work on "Australasia" in a revised and enlarged form. The first volume of the new edition, dealing with Australia and New Zealand, was published a few months ago. The second volume, which has just appeared, has for its subject Malaysia and the Pacific Archipelagoes, being an enlargement of the part devoted to that region in the original work. Dr. F. H. H. Guillemard is responsible for the new work, and he has performed his task so thoroughly that the present volume occupies nearly twice the number of pages previously allotted to the region with which it deals. The work is certainly the most interesting and accurate account extant on the tropical portion of the Eastern Archipelago.

STUDENTS of the anatomy of the horse will be glad to learn that the second volume of the elaborate "Topographische Anatomie des Pferdes," by Drs. W. Ellenberger and H. Baum, has been published by Paul Parey, Berlin. The first volume, dealing with the structure of the limbs of the horse, appeared in the spring of last year. The volume just received has for its subject the head and shoulders; while the third, which the publisher informs us will be issued early next year, will be devoted to the trunk. We shall review the work when it is completed. So far as we can at present judge, it promises to be a useful contribution to the literature of the subject, possessing both scientific and practical importance.

PROF. W. NERNST's important treatise on "Theoretical Chemistry, from the Standpoint of Avogadro's Rule and Thermodynamics," the German edition of which was enthusiastically received last year, has been translated by Prof. C. S. Palmer, of the University of Colorado, and the translation will shortly be published by Messrs. Macmillan and Co. The work is a development of Prof. Nernst's introduction to the "Handbuch der Anorganischen Chemie" of Dr. O. Dammer. It is, however, quite an independent text-book for students of the new physical chemistry, and includes the results of all recent investigations bearing upon that science. The book will serve at once both as a treatise in itself, and also as an introduction to, and companion in, the larger field covered by the *Zeitschrift für Physikalische Chemie* and the related literature.

ANOTHER scientific work which Messrs. Macmillan will shortly issue, is "Steam and the Marine Steam Engine," by Mr. John Yeo. The book is chiefly intended for naval officers, and for students of engineering in the earlier part of their training. It aims especially at giving a sound general knowledge of the propelling machinery of ships, and of various matters connected with its use and management.

IN "Darwinism and Race Progress," which Messrs. Swan Sonnenschein and Co. will shortly publish, Prof. Haycraft shows how the racial deterioration which would of necessity ensue upon our modern care of the sickly and enfeebled, may be counteracted by a keener public conscience. Our preservation of unworthy types by public and private charity is strongly animadverted upon, and with regard to intellectual development, it is pointed out that the present democratic movement, while it gives a chance to the clever and capable of becoming educated and well-to-do, entails upon them conditions which generally imply late marriages and relative sterility. Without supplementary action, nothing could be devised which would more effectually breed capacity out of the race.

TWO volumes have lately been added to the comprehensive engineering division of the Encyclopédie Scientifique des Aide-Mémoire, published jointly by Gauthier-Villars and Masson. They are "Les Chronomètres de Marine," by M. E. Caspari, and "Torpilles Sèches," by M. E. Hennebert. As is the case with all the volumes in the same series, the two new ones are practical handbooks of a very instructive character. In the former, the construction of chronometers, and the theory relating to it, are clearly described, and a deal of space is devoted to the effects of various conditions upon the rate, and also to the determination of the coefficients of the rate-formula. The determination of longitude by means of chronometers, and the methods of testing and comparing the instruments, are concisely described. Both M. Caspari's work, and that by Lieut.-Colonel Hennebert on torpedoes, bring together a lot of scattered information of great use to students of the subjects with which they respectively deal.

COMMERCIAL geography is just the kind of subject to be fostered by County Councillors, hence, from the time that the Technical Instruction Act came into operation, there has been an increasing demand for text-books upon it. The first edition of Dr. H. R. Mill's "Elementary Commercial Geography," in the Pitt Press Series (Cambridge University Press), appeared in 1888, when the boundary line of commercial geography was in a more or less nebulous condition. Thanks to the impetus that has been given to the subject during the past few years, the book has reached a second edition. The new issue is not, however, merely the original work reprinted, for it has almost entirely been rewritten. To quote the preface: "The book has been revised throughout by the aid of official publications, and the facts are as far as possible brought down to date. It is enlarged by treating more fully of the principles of commercial geography, by describing the African possessions of the European powers in greater detail, and by many small additions in every chapter."

These additions have enlarged the book from 132 to 181 pages, and have correspondingly increased its value. It would be difficult to find an elementary class-book of commercial geography constructed on better lines, or in which the information is more concisely and accurately stated.

The additions to the Zoological Society's Gardens during the past week include a Spotted Owl (*Athene brama*), four Grey Francolins (*Francolinus ponticerianus*), three Rain Quails *Coturnix coromandelica*), an Indian House Sparrow (*Passer domesticus*), two Red-headed Buntings (*Emberiza luteola*), two Nutmeg Finches (*Munia rubro-nigra*), a Spotted Turtle Dove (*Turtur meena*) from India, presented by Mr. E. W. Harper, a West African Love Bird (*Agapornis pullaria*) from West Africa, presented by Mrs. Robinson; a Reticulated Python (*Python reticulatus*) from Malacca, presented by Mr. Sigismund Bruzaud; an American Black Bear (*Ursus americanus*, var. *cinnamonea*) from the Rocky Mountains, two Common Cassowaries (*Casuarius galeatus*) from India, a Red-vented Parrot (*Pionus menstruus*), two Orange-flanked Parrakeets (*Brotogerys pyrrhopterus*) from South America, a Scops Owl (*Scops* ——) from Formosa, deposited; a Short-billed Toucan (*Ramphastos brevicarinatus*) from Central America, received in exchange.

OUR ASTRONOMICAL COLUMN.

Motion and Magnitude.—Students of elementary astronomy often believe that stellar motions in the line of sight soon produce changes in the magnitudes of stars. Motion towards the earth involves, of course, a certain increase of magnitude, and a motion of recession must carry with it a decrease, but the amount in the case of a star is far too small to be measurable, even if the magnitudes are observed during many generations. At the meeting of the Amsterdam Academy on November 24, Prof. Oudemans communicated the results of an investigation to determine exactly how long stars of which the velocity in the line of sight are known would have to go on moving, in order to produce a change of 0·1 magnitude. From his own list of parallaxes in vol. 122 of the *Astr. Nachrichten*, and Vogel and Scheiner's list of proper motions in the line of sight ("Potsdam Observations," vii. i. p. 153, 154), fourteen stars were selected, four of them receding from, and the remaining ten approaching, the solar system. Adopting a solar parallax = 8″·815, and the logarithm of the proportion of the increase of brilliancy for one magnitude = 0·400, he found that the period required is given by the formula

$$\frac{6195}{\text{parallax} \times \text{motion}}$$ years for stars that are receding from,

and $$\frac{5916}{\text{parallax} \times \text{motion}}$$ years for those that are approaching

to the solar system; the parallax being expressed in seconds, and the motion in geographical miles (1 geographical mile = 4·61 English miles). Aldebaran proved to be the only star of which the brightness could, since Ptolemy's time, have experienced a loss of 0·1 magnitude by its radial motion, provided that the parallax 0″·52, found by Otto Struve, is trustworthy. Elkin found a value = 0″·12, and adopting this value, the period becomes 4⅓ times longer. For the other stars the result was 5500 years at least for Procyon; while most of them gave ten-thousands of years as the result.

The Recent Transit of Mercury.—Details of several of the American observations are published in *Astronomical Journal*, No. 330. At most of the stations, some of the contacts could not be observed on account of clouds, but, on the whole, a fair amount of success attended the observers. Prof. Young observed the first and second contacts, and reports that there was a sort of "hardening" of the sun's limb close to the expected point of first contact a few seconds before the actual contact took place; he has now observed this phenomenon four times, and states that "it may be due to the planet's obscurvation of the brightest part of the chromosphere close to the disc of the sun, or to some diffraction effect at the limb of the planet." A large "black drop" was observed two seconds before the second contact. Prof. Todd failed to observe the contacts on account of unfavourable weather, but obtained some results during the passage across the disc. He says:—"The planet appeared perfectly circular, sharply defined about the limb, unattended by any halo or atmospheric ring, and of the same colour as the umbræ of the spots on the sun. No attendant satellite of Mercury was seen, nor could any bright spot be discerned upon the centre of the disc, although intently looked for. Any satellite smaller than 100 miles would have escaped detection."

The New Achromatic Object-glass.—*Engineering* for November 23 and 30 contains a full account of a fine 12½ inch equatorial that has just been built by Messrs. Thomas Cooke and Sons, York, for the new observatory at Rio de Janeiro, together with a sketch of the Buckingham Works at York. The description is accompanied with twenty-nine detailed drawings of the instrument. It appears that the works are the only ones in this country where every part of a modern astronomical telescope is constructed; with the exception of the actual making of the glass, everything is done on the premises, even the heavy cast-iron pillars being made in the firm's own foundry. The new instrument, with Messrs. Cooke's standard form of equatorial mounting for large refracting telescopes, is fully equipped for all branches of astronomical research. The clock, too, has all the latest improvements for adjustment. The object-glass is of the three lens form, invented by Mr. Taylor, who deserves the thanks of astronomers for producing an objective which, whilst made of durable kinds of glass, and of moderate focal length, is perfectly achromatic. How this end is attained was described in these columns on March 15 (vol. xlix. p. 464). A section of the lens is shown in Fig. 1. The first, L_1, is made of baryta light flint, having a refractive index of 1·5637 for the D ray, and its reciprocal of dispersive power is 50·6. The second lens, L_2, is made of a new glass known as boro-silicate flint. This glass has a refractive index of 1·54685 for the D ray, and the reciprocal of its dispersive power is 50·2. The third lens, L_3, is made of light silicate crown glass having the following characteristics: refractive index for D ray, 1·5109; reciprocal of dispersive power 60·4. By suitably proportioning the various radii of the lenses, the middle negative lens may be made to almost exactly compensate for the dispersion effected by the other two, and this without necessitating any exceptionally great focal length. If necessary this may be made so small as fifteen times the aperture, and there is no difficulty whatever in making a glass with a focal length of eighteen apertures. A small space is provided between the second and third lens, the object of this being to make the correction for spherical aberration as complete as possible; and when the thickness of this space is properly proportioned, there is an entire absence of spherical aberration for all colours of the spectrum. Object-glasses made on this plan have been tested by astronomers for visual and photographic observations. In both cases the stellar images showed no indications of residual colour, the lenses behaving just like the mirror of a reflector.

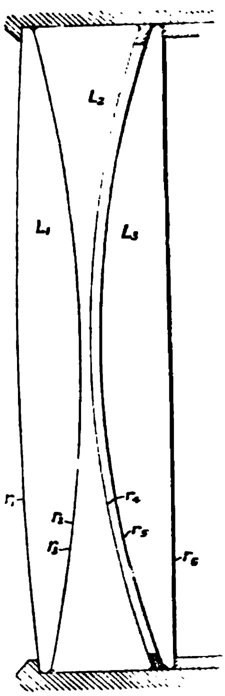

Fig. 1.—Section of the New Object-glass.

Ephemeris for Swift's Comet.—The surmise noted in these columns last week has proved to be correct. M. Schulhof shows pretty conclusively, in the current *Comptes-rendus*, that Swift's new comet is really identical with De Vico's comet 1844 I. The subjoined ephemeris is from one given by Prof. Lamp in the *Astronomische Nachrichten*, No. 3266.

Ephemeris for Berlin Midnight.

1894.	R.A. (app.) h. m. s.	Decl. (app.) ° ′	Brightness.
Dec. 13	23 21 36	−5 33·9	
,, 15	26 46	4 55·7	0·53
,, 17	31 52	4 17·9	
,, 19	36 54	3 40·5	0·48
,, 21	41 53	3 3·5	
,, 23	23 46 48	−2 26·9	0·43

The brightness of the comet on November 21 has been taken as unity.

A NEW STAR?—The Rev. T. E. Espin has announced that a very red star of the eighth magnitude, not in the Bonn Durchmusterung, was found by him on November 29, in R.A. 17h. 54·3m. Decl. + 58° 14′. The spectrum belongs to Secchi's Type IV.

PROF. VICTOR MEYER'S NEW METHOD OF DETERMINING HIGH MELTING POINTS.

A DESCRIPTION of improved apparatus for the determination of high melting points, by his admirable new method, is contributed to the current *Berichte* by Prof. Victor Meyer, in conjunction with his students Messrs. Riddle and Lamb. The simplicity of the method will doubtless cause it to take rank immediately among the standard processes for the determination of physical constants, and alongside the universally popular method of determining vapour densities, which we likewise owe to the distinguished Heidelberg professor. Naturally, however, operations at temperatures higher than those at which the hardest varieties of glass soften, must perforce be conducted in apparatus constructed of platinum, just as in the cases of the determinations of vapour density at the same high temperatures. One of the main advantages of the method is that it only necessitates the use of a very small quantity of the substance whose melting point is to be determined, thus enabling it to be extended to compounds of the most extreme rarity.

The method is based upon the principle of measuring the temperature by means of a miniature air thermometer constructed of platinum, the air contained in which is expelled, at the moment when the fusion of the substance under investigation occurs, by means of a soluble gas into a gas-measuring vessel filled with a liquid capable of dissolving the expelling gas. The substance whose melting point is to be determined is placed in a small and very narrow platinum tube, which is fixed to the bulb of the air thermometer during the operation, and both are immersed in a bath of a fused salt whose melting point is considerably below that of the substance under investigation. Hence the operation of determining a high melting point by this method is perfectly analogous to that usually adopted in determining ordinary melting points lower than the temperature of boiling mercury.

The air thermometer is simplicity itself. It consists of a spherical platinum bulb of about 25 c.c. capacity, from which rise parallel to each other two relatively long capillary tubes, also of platinum. One of the tubes passes down into the interior of the sphere, almost touching the opposite inner surface, while the other only just pierces the envelope. Both are bent at right angles at their upper extremities, in opposite directions. In order to eliminate all errors due to the capillary tubes a compensator is also employed, consisting of a long capillary U-tube of the same bore and bent at right angles at the extremities, so as to form an exact counterpart of the capillary portion of the air thermometer. The small tube containing the substance is firmly fixed by means of stout platinum wire so that its lower portion is in close contact with the sphere; the walls of the tube are of the same thickness as those of the sphere. The salt employed for the purposes of a bath is contained in a capacious platinum crucible, supported over a table furnace in a miniature basket of platinum gauze. One of the capillary tubes of the air thermometer is ready to be connected with an apparatus for generating pure carbon dioxide, and the other is attached to a gas-measuring burette similar to the well-known Schiff nitrogen apparatus, but somewhat narrower, and surrounded by the outer tube of a Liebig's condenser, through which a stream of cold water is continually passed. This arrangement enables the air to be collected and measured in the proximity of the furnace. The measuring burette is filled with a concentrated solution of caustic potash. The temperature of the water-jacket is measured by a thermometer immersed in a small accessory reservoir, through which the water passes immediately after leaving the jacket. A very simple device has been adopted for determining the exact moment when fusion occurs. Before the experiment the little test-tube is heated until the substance melts; a fine platinum wire, furnished with a thickened end, is then inserted in it, and allowed to become fixed by the solidification of the substance. The fine wire is then passed over a pulley some distance overhead, and the free depending end is attached to a weight; just below the weight a bell is hung.

When everything is ready for the actual operation of determining a melting point, the salt in the crucible is fused, the lower part of the air thermometer and its attached substance-tube are inserted in the bath of liquid, as is likewise the compensator, connection with the measuring burette is made, and the carbon dioxide apparatus is arranged to be delivering the pure gas. When the temperature of the bath at length attains that of the melting point of the substance, the portion of the latter in immediate contact with the walls of the platinum tube fuses, and instantly the wire is released, and the weight falls and strikes the bell. The moment the sound is heard, connection with the carbon dioxide apparatus is established, and the air contained in the thermometer is displaced and driven into the measuring burette. The compensator is similarly treated, and the quantity of air which it contained deducted from that contained in the thermometer. From the resulting volume, together with the knowledge previously obtained concerning the capacity of the thermometer and compensator and the known expansion of air, the melting point is obtained by a very simple calculation.

Four groups of interesting results have already been obtained by use of the new method, indicating the dependence of the melting point upon atomic weight. They are as follows:

Salt.	Melting point.	Salt.	Melting point.
Potassium chloride	800°·0	Potassium iodide	684°·7
Potassium bromide	722·0	Rubidium iodide	641·5
Potassium iodide	684·7	Cæsium iodide	621·0
Sodium chloride	815·4	Calcium chloride	806·4
Sodium bromide	757·7	Strontium chloride	832·0
Sodium iodide	661·4	Barium chloride	921·8

It will be observed that in the halogen salts of both sodium and potassium a diminution of melting point accompanies a rise in the atomic weight of the halogen; also that a lowering of the melting point accompanies a rise in the weight of the metallic atom in the case of the iodides of the alkali metals potassium, rubidium, and cæsium, while the reverse occurs with respect to the chlorides of the alkaline earthy metals calcium, strontium, and barium. Whether there is rise or fall of the melting point with ascending atomic weight, however, the salt of intermediate molecular weight invariably exhibits an intermediate melting point.

A. E. TUTTON.

SCIENCE IN THE MAGAZINES.

THERE are very few articles on purely scientific subjects in the magazines received by us this month. Apparently the magazine-reading public thinks a scientific pabulum unsuitable for Christmas reading; or is it that men of science are too deeply engrossed in their researches to cultivate the art of writing interestingly upon the wonders of nature? Literary men frequently play fast and loose with natural phenomena and laws, and are often pilloried for doing so; but, on the other hand, many men of science do not pay due regard to the literary polish which is essential to an attractive style.

The first number of the *Fortnightly* under the new editor, Mr. W. L. Courtenay, contains two articles of interest to our readers, one on "A True University of London," by Mr. Montague Crackenthorpe, and the other on "The Spread of Diphtheria," by Dr. Robson Roose. Mr. Crackenthorpe deals broadly with the whole question of the expediency of establishing in London a University which shall teach as well as examine. He defines the work of a true metropolitan University as follows: (1) To do the work of the higher teaching by its own professorial staff, and to superintend and aid its being done by other educational agencies in the metropolis. (2) To examine and to grant degrees, but to grant them as a mark of success in regular and systematic courses of study, rather than in the display of hastily acquired, and, therefore, ill-digested knowledge. (3) To stimulate scholarly and scientific research by means of well-equipped libraries, laboratories, and other like apparatus, and by the institution of public lectures of an advanced character, like those of the Sorbonne and the College de France. The scheme drawn up by the Gresham Commissioners satisfies most of these requirements, and a *deus ex machina* in the shape of a Statutory Commission is all that is wanted to establish it.

So much attention has recently been given to the new treatment of diphtheria, that Dr. Roose's sketch of the history of the complaint, and the circumstances which tend to promote its spread, comes very opportunely. His description of the measures calculated to check the prevalence of the disease, and of the remedy lately introduced, is clear and concise, whilst the following statement, though commonly known in the scientific world, will remove the misapprehension that exists in the minds of a large section of the general public:—"Löffler and Klebs discovered the microbe of diphtheria, and studied its life-history; Roux and Yersin demonstrated that the bacillus was capable of evolving toxic material, and Behring crowned the edifice by discovering the antidote."

An address by Prof. G. W. Prothero, on "Why should we learn History?" contained in the *National*, would at first hardly seem to be a subject for comment in these columns. There is, however, much in the address worth noticing here, for Prof. Prothero shows that history, if not strictly speaking a science, may be taught in a scientific way. Let us briefly state his argument. There are many gaps in history, but in every science there is a lack of information on certain points. Even astronomy, the most exact of the sciences, has its dark spots, and there are shady places in evolutionary biology. Thus, so far as imperfection of knowledge goes, history and science only differ in degree. A greater difficulty, perhaps, is that the historian cannot employ experiments either to discover facts or to test observations; but here again it suffers in company with geology and other branches of natural knowledge concerned with the past. History is therefore not disqualified from being a science because it is not experimental. The infinite variety and extent of historical phenomena, and the presence of the human element are, however, "obstacles which, it must be allowed, check history on the threshold of science. If indeed the term science is to be restricted to the knowledge and application of general laws—if that alone is science which can foretell with certainty the occurrence of certain results—if science deals with no phenomena but such as can be exactly weighed and measured—then history is not a science at all. But this is surely to restrict science within too narrow limits. All sciences are not equally exact or equally capable of generalisation. . . . There is, in fact, a regular gradation from the sciences of abstract reason and mathematical formulæ, through the phenomena of the inanimate and the animate world to the world of man." But, *pace* Prof. Prothero, if history be granted a place among the sciences, it must be scientific in the ascertainment of its facts. Take the Black Death as an illustration. The vague and exaggerated statements of certain chroniclers of its ravages may be taken as evidence, or the more laborious process of searching the registers of the time may be explored. The difference is that one of the ways is scientific, while the other is unscientific. In the drawing of conclusions, also, "there is the same distinction between scientific and unscientific work as there is in the ascertainment of historic facts. For instance, Buckle, in illustrating his theory that national character depends largely upon food, attributes the weakness of the Hindoos to an almost exclusive diet of rice. A striking but misleading generalisation, for, as Sir H. Maine has pointed out, the great majority of the Hindoos never eat rice at all. . . . There is, then, a scientific way as there is an unscientific way of studying history. If treated one way, its results are guess-work and delusion; if treated another way, if industry, reason, and sober judgment are brought to bear, its results are in many cases matter of certainty, in many others matter of at least high probability. And, if we except the science of mathematics, what more can be said of any science?" The main object of Prof. Prothero's address was to show that historical study exerts considerable influence upon the mind and character. This is certainly the case, and if the student is trained on the lines indicated in the foregoing, intellectual results of the highest order must follow.

The great landslip which caused the formation of the Gohna Lake, Gurhwal, in the central Himalayas, has led Mr. W. M. Conway to write on "Mountain Falls" in the *Contemporary*. This catastrophe, however, is only used as a peg upon which to hang an account of the great Alpine landslip which buried part of the village of Elm, in Canton Clarus, thirteen years ago. The *Contemporary* also contains a metaphysical article by Emma Marie Caillard, in which cosmic and ethical processes are discussed, and Prof. Huxley's opinions on evolution and ethics are criticised. Prof. Huxley is also involved in a paper on religion and science, contributed by A. J. Du Bois to the *Century*. Another article for abstract philosophers is Prof. Seth's second paper on "A New Theory of the Absolute."

Sir Robert Ball contributes to *Good Words* another of his interesting—albeit superficial—papers on great astronomers, the subject being Sir John Herschel. *Chambers's Journal* contains the usual complement of chatty articles, among which we notice one on smoke absorption, descriptive of Colonel Dulier's patent system of removing the soot and sulphurous acid from the products of combustion, by treatment, before passage into the chimney, by both steam and water; and another on remarkable hailstorms.

A passing reference will suffice for the remaining papers on scientific topics. The result of prematurely releasing a chrysalis from its cocoon, a subject on which we published a letter by Dr. L. C. Jones in our issue of November 22 (p. 79), serves Mr. W. C. Wilkinson as the theme of a poem in the *Century*. St. George Mivart writes popularly on "Heredity" in the *Humanitarian*, his paper dealing chiefly with Prof. Weismann's speculations. A posthumous paper of Richard Jefferies' appears in *Longman's Magazine*, and Mr. Phil Robinson contributes a facetious paper on rattlesnakes to the *English Illustrated*. In addition to the magazines and reviews named in the foregoing, we have received *Scribner*, *Cassell's*, and the *Sunday Magazine*; but these do not contain any articles that can be commented upon here.

OYSTER CULTURE ON THE WEST COAST OF FRANCE.[1]

AT the request of the Lancashire Sea-Fisheries Committee, I spent some time, last June and July, in investigating the various methods of shell-fish culture in use along the western coast of France from Arcachon in the south to Brittany in the north. There can be no doubt that there are extensive and flourishing shell-fish industries along the French coast, and one is struck very forcibly with the admirable manner in which the people seem to make the best of unfavourable conditions, and to take full advantage of any opportunity given to them by nature. Few places on any coast could look more desolate and forbidding than the vast mud swamps of the Bay of Aiguillon, and yet by means of the "bouchot" system many square miles of this useless ground have been brought under cultivation, and an industry established which supports several villages. Then again, the neat little enclosures along the beach at many places, carefully tended by the owners at low tide, remind one constantly of market gardening, and enforce the truth of the idea, long familiar to the biologist, and now beginning to be more generally recognised, that the fisherman should be the farmer, not the mere hunter of his fish, and that aqui-culture must be carried on as industriously and scientifically as agriculture.

In addition to industry and care on the part of the fisher-folk, women as well as men, the success of the shell-fish industries in France is largely due to the encouragement and wise assistance of the Government, especially in the regulation of general oyster-dredging and the reservation of certain grounds for supplying seed. The practical question—and one of enormous importance—is: Is there anything special in the conditions in France, either of the land or of the water, which would render their methods inapplicable to our more northern shores? I do not believe that the question can be satisfactorily and finally answered until some experimental cultures on a fairly large scale have been tried; but a consideration of the details and results of the French methods will at least give us some idea of which experiments are worth trying, and of the localities which might be cultivated with most prospect of success.

[1] Abstract of a report, by Prof. W. A. Herdman, F.R.S., to the Lancashire Sea-Fisheries Committee.

The leading characteristics of French oyster culture are (1) that the whole is under the regulation and supervision of the State, concessions of ground being given to individuals or companies (*e.g.* at about 30 francs the hectare at Arcachon) for the purpose of forming oyster "parcs"; (2) that certain grounds are set aside or preserved as banks of breeding oysters to supply the spat; and (3) that the whole process of raising the spat, and rearing and fattening the oyster, is not carried on at one locality, but is subdivided and specialised, spat-production taking place best at one locality, such as Arcachon, and fattening for market at another, such as Marennes.

Two species of oyster are cultivated, *Ostrea edulis*, the ordinary rounded flat oyster of north-west Europe; and *O. angulata*, the elongated Portuguese oyster. The latter, although increasing in numbers in some places, and becoming of considerable commercial importance, is not so highly thought of as is *Ostrea edulis*.

There are now only two places on the coast of France where spat is produced in sufficient quantity to be of commercial importance. These are Auray, in the north, and Arcachon, in the south, and these two localities supply all the other oyster culture centres in France, and even export to other countries. One merchant I met at Arcachon told me that he had already sent eleven millions of oysters to London that season.[1] I visited in all about ten different oyster-culture centres; but as several of these showed nothing special, they need not be mentioned. The arrangements for the capture and rearing of spat were best seen at Arcachon, and for the further rearing and the fattening of the adults at La Tremblade and Marennes on the estuary of the Seudre. At Arcachon I was fortunate in enjoying the hospitality of the excellent Biological Station, which was established nearly thirty years ago by La Société Scientifique d'Arcachon, and which was made use of by Paul Bert in 1867 for his observations on the physiology of marine animals.

Arcachon presents remarkable facilities for the study of shallow-water marine forms, and is of great interest to the biologist, as well as to the ostreiculturist. Its vast inland sea (Bassin d'Arcachon), which is about 80 kilom. in circumference, contains at high tide about 15,000 hectares of area, and is, over the greater number of the channels, about 5 to 10 fathoms in depth, while two-thirds of the whole area dries at low tide. In the middle of the "bassin," and north of the town of Arcachon, is a small island, Ile des Oiseaux, and on the shores of this, and on various other flat shallow parts which are exposed at low tide, and which are called "crassats," are situated the oyster "parcs." Some of these areas are reserved by the State for the purpose of producing spat, a wise precaution, although some of the parqueurs think the State reservations unnecessary, as there are so many adult oysters over the ground that plenty of spat is sure to be produced. Certainly during the time of my visit, which was just when the free-swimming embryos were settling down, the water over the parcs seemed to be swarming with them, and the spat was making its appearance over all sorts of suitable submerged objects. The summer of 1893 was, however, a particularly good season, which the parqueurs attributed to the great heat. Probably calm weather and absence of rain during the critical period when the young oysters are free-swimming, and then settling down, has as much to do with a heavy fall of spat as the actual temperature.

The oyster reproduces at Arcachon between May and the beginning of July, and the young animal leads a free swimming existence for about a week before settling down as spat. The parqueurs examine carefully the condition of the spawn in the old oyster, and at what they consider to be the proper time (generally about the end of June) for catching the deposit of spat, they place their "collectors" in position. It is of importance that the collectors should not be put in the water too soon, as they are liable to become coated with slime and sediment, which will prevent the young oyster spat ("naissain") from adhering. The collectors are crates ("gabarets" or "ruches") of earthenware tiles, coated with a limy cement which gives them a whitewashed appearance. The tiles are like ordinary roofing tiles, about fourteen inches long by six inches at one end and five at the other, and half an inch in thickness. The cement with which they are coated is made of lime mixed with sea-water and a certain amount of sand, so as to form a creamy paste. Different proprietors use slightly different proportions of lime and sand. The process of coating ("chaulage") adds from one-sixteenth to one-eighth inch in thickness to each side of the tile. It has to be done with some care, so that the limy layer may be of the right nature, sufficiently strong and adhesive, and yet readily detachable when the time for "détroquage" comes, so that the young oysters may be removed from the tiles without injury, and without the necessity of breaking up the tiles, as used to be the case. By the present method the little oysters and film of cement can be flicked off rapidly by a skilled hand with a square-ended knife, and the tiles preserved for use again the following year. A dozen or more millions of these tiles are probably employed each year at Arcachon. The prepared tiles are arranged in alternating rows lengthways and breadthways inside cases made of strips of wood, so that the water may flow in readily between and around them. The cases of collectors I measured were about 6 feet × 2 feet and 3 feet in height, each holding 120 tiles arranged in ten layers. The alternating arrangement of the layers is intended to break up the currents of water as the tide runs through the "ruche," form eddies, and so give the young oysters a better opportunity of affixing themselves to the tiles. The tiles are all placed with the convex surface upwards, as it is very important that there should be as little opportunity as possible given for the collection of any fine sediment in which the young spat might be smothered. The arrangement of tiles above described is now considered the best at Arcachon. Various other arrangements have been tried, and may be suited to special conditions of bottom or depths of water.

I was very fortunate in seeing some of the tiles just after the young oyster spat had been deposited, and photographed such a tile covered thickly with the minute amber-coloured specks. There may be several hundred such young oysters on one side of a tile. During my stay at Arcachon I found that the temperature of the water varied from 74°F. to over 80°F., and the specific gravity from 1·022 to 1·024. However, it is known that no such high temperatures are really required for spat production, since, *e.g.*, Captain Dannevig has had an abundant deposit of spat in his pond near Arendal in Norway, where the July temperature of the water was only 63° F. To compare these with our own district, we find that in the same week of July 1893 the water off the south end of the Isle of Man was on the average about 60° F. with a specific gravity ranging from 1·025 to 1·026, while shore pools near the Biological Station at Port Erin, comparable as to exposure with the oyster parcs at Arcachon, reached as high a temperature as 76° F. Dr. Bashford Dean[1] and other authorities state as their opinion, that a low specific gravity is necessary for a good deposit of spat, but there is no unanimity on this point amongst the practical men at Arcachon (some of whom are keen observers, and are in the habit of taking the temperature and specific gravity).

After removal from the tiles, those young oysters which are not sold to "éleveurs" away from Arcachon are kept for another year or two in the parcs. They are placed at first in flat trays having a floor and lid of close galvanised wire netting, of about half-inch mesh, and these trays ("ambulances" or "caisses ostreophiles") are placed between short posts in the water on the oyster parc, so that the tide can run freely through them, supplying the oysters with food and oxygen. They measure about 6 feet by 4, and are 6 inches deep. They serve to keep the young oyster, during the early period of its life, out of the sediment, and they also protect it from its numerous natural enemies, such as the starfishes and crabs, which manage to suck or pick out the soft body, and whelks, such as *Purpura*, *Murex* and *Nassa*, which can bore a hole through the shell. The ambulances are constantly looked after by the oyster men and women, who come at low tide, when they are exposed, open the lids, and pick over the contents, removing enemies and impurities which may have got in, taking out any dead oysters, and rearranging those that are left, so that all may have a fair chance of obtaining food and growing normally. The young oysters grow rapidly in the ambulances, and soon have to be thinned out. The larger ones are removed, and if large enough are thrown into the open areas of the parc. In this way, by

[1] Two-year olds, measuring 5 to 6 cm. across, cost at the rate of 12 francs per 1000, and somewhat older ones, measuring 6 to 7 cm., 25 francs per 1000. These prices include packing and carriage as far as Bordeaux, where they meet the steamer. On an average only 1 per cent. die on the journey. From the middle of March to the middle of April is the best time to send young oysters for stocking purposes to England. Before that it is liable to be too cold in England, and later it is too hot in Arcachon for transportation to be effected safely.

[1] Various important papers in Bulletin U.S. Fish Commission.

thinning out, rearranging, and adding fresh supplies, relays of young oysters in their first year may occupy the ambulances for eight months, although an individual oyster may only be in for a month or so.

Eventually all the oysters not sold to éleveurs get transferred from the ambulances to the open rectangular areas, like little fields, which make up the rest of the parc. The low banks bounding these areas are formed of two parallel rows of close-set vertical bunches of the local heath, *Erica scoparia*, with the space between, a foot or more wide, filled in with masses of a tenacious clay obtained from the Ile des Oiseaux. Planks of wood and stakes, to strengthen the boundary, are also used in places, and at one corner a sluice is formed, so that the water at low tide may either be retained to a depth of 6 or 8 inches, or allowed to run off as required. About one million oysters can be accommodated in each little field, which is about at the rate of 125 to the square metre. Going thoroughly over a parc, partly in a boat and partly by wading, gives one an excellent idea of the extensive and profitable system of aquiculture practised at Arcachon.

Between neighbouring oyster parcs, and surrounding the "concessions" of the various proprietors, run lanes of water about 4 metres wide. These give ready access to the parcs, and can be traversed by the long gondola-like boats of the parqueurs. The lanes are bordered by rows of tall saplings with bunches of twigs left on. These are called "pignons." They keep waving in any slight breeze, and give a characteristic appearance to the scene. The oyster men declare that they are of use in frightening away fish, and especially the voracious ray *Myliobatis*, which might otherwise do great damage in the preserves. Possible depredations of another kind are guarded against by the "pontons," or large barges, moored at the corners of the parcs in which the "gardes des pêches" live.

Great numbers of the oysters bred and reared through their early stages at Arcachon are sent to Marennes and La Tremblade, in the flat district on both sides of the estuary of the Seudre, to be fattened in a *parc d'élevage*, and "greened" by feeding upon the diatom *Navicula fusiformis*, var. *ostrearia*. Wide canals from the estuary lead the sea-water inland, and supply the numerous "claires," which are merely shallow artificial ponds excavated in the clay and marly soil. In spring and early summer the muddy floor of the claire undergoes a good deal of preparation by digging, cleaning, draining, and exposure to sun and air, in order that later on, when sea-water is readmitted, at first in small quantity, it may be in what has been found by experience the most favourable condition for the growth of the desired kinds of lower algæ. These soon cover the floor with a dense green growth, which the éleveurs recognise as being of great importance to the nutrition of the oysters. Samples of the growth which I collected from the bottoms of several claires consisted of *Cladophora flavescens* and *C. expansa*, along with *Spirulina tenuissima* and a *Lyngbya* and little tufts of *Calothrix*, while a more detailed examination with the microscope shows that these plants are teeming with small animals and other forms of life, and nearly everything is covered with innumerable diatoms. Probably the larger green algæ, thought so much of by the éleveurs, are only of importance in oyster culture in providing points of attachment and shelter or favourable environment for the microscopic forms of life, and especially for the diatoms. It is well known that diatoms form a most important constituent of the food of oysters, and that the greenish blue tint of the celebrated Marennes oysters is due to the presence in the claires of enormous quantities of *Navicula fusiformis*, var. *ostrearia*, upon which the oysters feed. This form is found in our own fishery district in the estuary of the Dee (and probably elsewhere), although not abundantly; but it is probable that there are various other allied diatoms that would do equally well for rearing and fattening oysters on, and as a matter of fact the examination of the contents of an oyster's stomach shows that the food consists of a number of different kinds of diatoms as well as other minute organisms.

Altogether, all the evidence I was able to collect shows, I think, that the bottom of a claire is teeming with microscopic life, and that it is probably this rich feeding *alone* which is necessary in order to bring the oysters, in a very short period—a few weeks usually, sometimes ten days or a fortnight is sufficient—to the desired condition of fatness and flavour. The autumn and early winter months are said to be the best for fattening and greening.

I shall have to omit all reference to the industries at Pointe le Chapus, at the Island of Oléron, at La Rochelle, at Les Sables d'Olonne, and at Le Croisic—except a brief explanation of the basins of "dégorgement" seen at Le Chapus and elsewhere. These are shallow tanks, high up on the beach, with smooth bricked or tiled floors, so that they can be kept clean and free from mud. Their purpose is to enable the oysters taken fresh from the parcs and claires, and which naturally have some fine mud and food-matters of a decomposable nature clinging to them, both externally and internally, to lie for a few days in clean water, and so get rid of their impure mud and excreta before being packed up and sent off on a journey. The oysters also become accustomed in these basins, which can be emptied and filled with water periodically, to close their shells and stand prolonged exposure to air.

I do not see that the French shores are, in any important respects better fitted for shell-fish culture than some parts of our own Lancashire and Cheshire coast.[1] The deposits, both littoral and submarine, are, on the whole, much the same, the fauna, both macroscopic and microscopic, is scarcely appreciably richer, and although the temperature of the water is decidedly higher in the south—probably on the average about 10° F. higher in summer—I do not think that that is an essential condition, *so long as the winter temperature of our water does not get too low*. It would certainly be necessary, I think, to keep our oysters completely submerged during the winter months; but there are several places in the estuaries of the Dee and the Ribble, and in the Barrow Channel near Roe and Peil Islands, where "littoral" cultivation in summer might be combined with "bedding out" in winter—somewhat as is done at present with American oysters in the estuary of the Wyre, near Fleetwood. As to the other conditions—of bottom, of water, and of food, several places in the Barrow Channel and in the Dee estuary seem to me to be well fitted for oyster culture.

ENDOWMENT FOR SCIENTIFIC RESEARCH AND PUBLICATION.[2]

I.

TWENTY years ago Prof. Tyndall delivered in New York and in other cities of this country a series of lectures upon light. The last of the series was an impressive plea for a more thorough prosecution of original research in pure science; and incidentally, for the need of endowments to maintain it. I was fortunate in having the opportunity to listen to that remarkable course of lectures, and to that plea for science. Its impression has never left me. The impression was the deeper, because Tyndall set upon it the seal of self-denial. Some 30,000 dols., nearly the entire net proceeds of his lectures in the United States—money for which he undoubtedly had abundant use in his own affairs, or at least in the prosecution of researches in his own country, and which by all precedent and the example of other lecturers he would have taken with him—this he has given to the science of this country, endowing therewith, in 1885, three scholarships for the prosecution of original research in physics, one under the direction of Columbia College, one under Harvard, and a third at the University of Pennsylvania.

The truths uttered and the example set by this self-denying master have already many times borne fruit. The late President Barnard, of Columbia College, who was a warm supporter of Prof. Tyndall when here, bequeathed to Columbia upon his decease a few years since the sum of 10,000 dols. for the endowment of another fellowship for the encouragement of scientific research, upon substantially the same terms as those of the Tyndall scholarships. In other parts of the country there have been some other endowments for similar purposes. In the last year Columbia has also received 100,000 dols., the munificent bequest of Mr. Da Costa, for the establishment of the department of biology. Although this bequest is not primarily for the prosecution of original research, it is not restricted by hampering conditions, and will to some extent, it is hoped, admit of a direct and continuous support of the highest and most advanced studies.

The appeal made by Tyndall has been often renewed by

[1] This, being a report to the Lancashire Sea-Fisheries Committee, is only concerned with localities within the Fishery District.

[2] Address delivered by Mr. Addison Brown, at a meeting of the Scientific Alliance of New York. (Reprinted from Smithsonian Report, 1892.)

scientific men; by the heads of universities; by the presidents of scientific associations, here and abroad; and by none, perhaps, more eloquently than by Dr. Edwin Ray Lankester, in his address before the biological section of the British Association at Southport, in 1883.

What shall we say to the call and the examples of such men? Was the gift of Tyndall based only upon an idle fancy? Or was it the result of a clear perception of a profound truth, viz. America's need of that money as a stimulus and support to more scientific research; the call on him being felt to be the more imperious, because the need of it was so plain to him, while obscure to others; and making his act, therefore, a noble instance of self-renunciation in an unappreciated cause?

"To keep society as regards science in healthy play," he says, "three classes of workers are necessary:

"(1) The investigator of natural truth, whose vocation it is to pursue that truth and extend the field of discovery for truth's own sake, without reference to practical ends.

"(2) The teacher, to diffuse this knowledge. . . .

"(3) The applier of these principles and truths to make them available to the needs, the comforts, or the luxuries of life. . . .

"These three classes ought to coexist and interact. The popular notions of science . . . often relate, not to science strictly so-called, but to the application of science."

The great discoveries of scientific truth, he continues, are "not made by practical men, and they never will be made by them; because their minds are beset by ideas which, though of the highest value in one point of view, are not those which stimulate the original discoverer."

In a chance conversation, a few weeks since, I received a confirmation of these words, so direct and unexpected, that it may bear citation. I was talking with an electrical expert who had made several very interesting and important inventions. I asked him of how much importance he conceived that the scientific men of the closet, the original investigators, so-called, had been in working out the great inventions of electricity during the last fifty years—the telegraph cables, telephones, the electric lighting, and the electric motors; and whether these achievements were not in reality due, mainly, to the practical men, the inventors, who knew what they were after, rather than to the men of science, who rarely applied their work to practical use?

"Not at all," he said, "the scientific men are of the utmost importance; everything that has been done has proceeded upon the basis of what they have previously discovered, and upon the principles and laws which they have laid down. Now-a-days we never work at random. Look at that electric light! Of the energy expended in producing it, only 7 per cent. appears as light; the rest, 93 per cent. is wasted, mainly in heat. We are all now trying to prevent this enormous waste. I want to reverse that proportion; but if I can reduce the waste to only 33 per cent. a patent of my invention will be worth millions of dollars for its economy in production. In seeking this we do not work at random. I go to my laboratory; study the applications of the principles, facts, and laws which the great scientists like Faraday, Thompson, and Maxwell have worked out, and endeavour to find such devices as shall secure my aim."

This is but an expression, in another form, of what Tyndall said twenty years ago: "Behind all our practical applications there is a region of intellectual action to which practical men have rarely contributed, but from which they draw all their supplies. Cut them off from that region, and they become eventually helpless."

What is true in one department of natural science is, I apprehend, equally true in all. The practical men do not work at random, but upon the basis of what scientific research and publication have previously put within their grasp.

It is evident, therefore, that not only the advancement of knowledge itself, but all possibility of any continuous advance in those great improvements which are to mitigate the sorrows, and promote the health, the conveniences, and the comforts of men, is vitally dependent upon the progress of scientific research. In recent years how marvellous have these improvements been! Besides those that are most common and familiar to all, what miracles, almost, have been achieved through the photograph, the spectroscope, the microscope; by the discovery of the sources of fermentation and of putrefaction; by the discovery of anæsthetics and the application of antiseptic methods in surgery, and in the treatment of other lesions! These latter discoveries alone have ameliorated beyond expression the sufferings of man; they save more lives than war and pestilence destroy, surpassing even in that regard the safety lamp of Sir Humphrey Davy—an invention which at the time it was made, was said to have exceeded every previous discovery as a means of saving human life, except, possibly, inoculation for smallpox.

This vital relation between the advancement of knowledge and the welfare of man furnishes an all-sufficient reason for the continuous and never-ending prosecution of original research. Of necessity the original work of discovery must always lead; that must always precede the practical applications. The necessity for such research must therefore continue so long as science and human society endure. As there is no limit to the advance of knowledge, so there can be no limit to the benefactions it is capable of conferring upon mankind. The more rapid the advance, the more speedy the enjoyment of its fruits. In this relation alone the need of ample provision for scientific progress is one that addresses itself equally to the nation, to the State, to philanthropists, and to all who would advance the welfare of man on the broadest and most enduring lines.

How shall such research be maintained and extended? The investigator of pure science does not work for profit. His discoveries are not marketable. The law allows no patent upon a principle of nature or the discovery of a new truth. Newton could not patent the law of gravitation, nor Volta the galvanism of the voltaic pile; nor Ehrenberg and Schwann the discovery of the widespread influence of bacteria; nor Faraday, nor Henry, electro-magnetism; nor Joule, his correlation of forces; nor Jackson, his anæsthetics; nor Lister, his antiseptic treatment; nor Koch, nor Pasteur, their discoveries of the bacilli, the destruction of which may lead to the cure or amelioration of terrible diseases. To the practical men and to the inventors, on the other hand, who apply to the specific wants of men the truths and principles which the men of science have made known to them, the law, in the form of a patent, gives a monopoly of from fourteen to twenty-one years. They thus obtain, as a rule, a reasonable, and, in some cases, even an excessive, pecuniary reward. In this country alone nearly 500,000 patents have been issued; they are increasing at the rate of about 25,000 per year. In the extreme multiplication of patents affecting a large part of everything we use, the whole world, it might almost be said, is paying tribute to the inventors and practical men; while to the original discoverers, who have made so much of all this possible, there is no promise of pecuniary reward.

This is not said by way of complaint. In the nature of things it is scarcely avoidable. The aims, the motives, the methods, and the genius of the two classes of minds are and ever must be widely distinct. Original discoverers cannot be turned aside from their special work to become mechanics and inventors without infinite loss. Prof. Henry had one form of the electric telegraph in actual use some years before Morse conceived it.[1] But how great would have been the loss to science, without any corresponding gain, had Prof. Henry in 1830 turned away from pure science to do the subsequent work of Morse in adapting the telegraph to common and valuable use!

Research in pure science can never be made a self-supporting pursuit. It can never, therefore, be carried forward broadly, and continuously, and effectively, except through men sustained by some form of stipend or endowment. Occasionally, it is true, men of independent fortune, like Harvey, and Darwin, and Lyell, and Agassiz, have devoted themselves to original research upon their own means, and have accomplished most important results. But these instances are rare. Many other persons, too, with aptitudes and tastes for research, though not following a scientific career, have carried on private researches in the intervals of leisure stolen from the exacting demands of professional or business life; and these have, in the aggregate, added no small amount to the common stock of knowledge.

It is no disparagement, however, of these subordinate workers to say that nearly all the great discoveries, and nearly all the great advances along the lines of knowledge, have been achieved by men who in the main have devoted their lives to the work, and have been supported through institutions or endowments which made this devotion possible. Government appointments, professorial chairs, or salaried positions in scientific institutions of some kind, have been and must continue to be our chief dependence. And it is manifest that these can only be maintained by Government aid, or by the bounty of private in-

1 "Smithsonian Report," 1878, pp. 159, 262

dividuals. The former is mainly the European system; the latter, in the main, is ours. There, universities are founded by the Government; here, chiefly by the people.

In Germany there are twenty-one universities maintained by the Government. In each of these, as Dr. Lankester states, there are five independent establishments in the department of biology alone, viz. in physiology, anatomy, pathology, zoology, and botany. At the head of each of these establishments there is a professor, with two paid assistants, making altogether about 300 for biological research in Germany; and he estimates about one-quarter of that number in the same department in England. In all the sciences, therefore, there would probably be found in Germany from 800 to 1000 persons of high scientific attainments, supported by the Government in the universities, who are regularly and systematically engaged in the discovery of new scientific truth. For it is there made both the object and the duty of the professors of natural science to carry on original investigations by work in the laboratory. Their positions are obtained through previous distinction in such investigations, and it is for this work that their small but fixed stipend is paid by the Government.

In the College de France, also maintained by the Government, there is the same requirement, though with a larger salary to the professors, and with the added duty imposed on them to deliver to the students about forty lectures yearly upon the subjects of the professors' researches; while in Germany the professors also receive from each student who attends their lectures, a moderate fee, which serves to increase their meagre stipend, as well as to stimulate their activity and usefulness. Under this system, Germany has become the greatest school of science, and the resort of the whole world.

In this country the opposite system prevails. The colleges and universities are mainly private foundations, dependent on private gifts and endowments. The colleges are unwisely multiplied. All are more or less cramped for money. This limits the number of professors and assistants appointed for instruction, and crowds them with routine work. The result is that in all but a few colleges, and in these until comparatively recently, the duties of instruction have left to the professors but little time or opportunity for the prosecution of original investigations; and these with but poor equipment and inadequate means.

In not one of all our colleges and universities, so far as I have been able to ascertain, is there a single professorship endowed or founded, even in part, for the avowed object of original scientific research. Instruction, not discovery, is the only avowed object. It is to the great credit of American professors and teachers that, with so much routine work on their hands, and so little leisure for research, they should have accomplished by purely voluntary studies so much as is shown in their contributions to our scientific publications.

To what is said above, perhaps a virtual exception should be made as respects our astronomical observatories, in which, the labours of instruction being less, original work has been perhaps expected, and has been accomplished with most signal success. To some extent this may possibly apply to our medical schools also. And in other departments, generally, wherever time and opportunity have been afforded, much original work has been done by our professors; some of it of the first class. This is attested, not to mention living instances, by the work of Prof. Henry at Princeton, Dr. Torrey at Columbia, Dr. Silliman at Yale, Dr. Gray at Harvard, and many others that might be named. In a number of the States, also, and at Washington, there have been maintained by the State or nation a number of scientific men, in connection with certain State or national interests, who have accomplished most important results; of these, Dr. James Hall, of this State, is a conspicuous instance. At Harvard and at other colleges some noble opportunities for special study have been also provided in their scientific schools and museums; notably in the zoological museum, the Jefferson Physical Laboratory, and the Peabody Museum of Archæology at Cambridge, and also in the department of hygiene at the University of Pennsylvania. But in most of these the great complaint is the lack of necessary endowments to make possible the active advanced work in original discovery for which those institutions are designed. In the Peabody Museum there was in 1891 a gift of 10,000 dols. by Mrs. Hemenway to establish a post-graduate fellowship; and also a gift of like amount by Mr. Wolcott, for the general support of the museum's work. New York also has within a few years past seen spring up almost as by magic, through the efforts of a single leading spirit, seconded by other public-spirited men and women, and by municipal aid, a museum of natural history that bids fair to stand in the front rank of scientific opportunities; but the endowments of fellowships and professors necessary to make its opportunities available in active research are as yet wanting.

England holds a position midway between the United States and Germany. Her scientific men lament her deficiencies. They are striving to increase their means for scientific work, and are doing so yearly.

If experience teaches anything, it is that no broad and general development of scientific work of the first class is possible, except either through independent establishments for special work, or else by the university system, in which professors in science and their assistants are first selected on account of their previous distinction in original research, and are then appointed to continue that work, and in the teaching of students, to transmit to them the zeal of discovery and the true methods of advance.

It matters little whether the support of the university or of special institutions for research comes from the Government or from private endowment, provided the provision is adequate and constant. The difficulty with us has been, and still is, that funds are insufficient, the means and equipment inadequate, and the time allowed to the professors for research insufficient. There has been too much of the schoolmaster, and too little of the real professor. Too great absorption of the professor's time in the work of instruction is injurious to both teacher and pupil. The most stimulating of teachers is he who by daily experiment is in vital touch with nature—he who brings from the fires of the laboratory the warmth, the illumination, and the inspiration of his own researches.

This is now well recognised; and so far as their means will permit, the leading colleges are by degrees relieving their professors of the work of elementary instruction, so that they may the better prosecute original researches, and at the same time become best qualified for the highest work of instruction. This system will doubtless demand watchfulness and discrimination. To prevent abuses, regulation and responsibility may have to be imposed. But it involves the appointment of additional instructors. It requires added means. And this is indispensable as a part of the transition of our leading colleges to the university system. It is indispensable, also, if we are to have in this country any considerable systematic prosecution of original research. We must use existing instrumentalities and existing institutions. And all experience shows that outside of the few Government positions, and in the absence of special institutions for research, the professorial chairs are best adapted to such investigations. No greater service could be done to science than to make such endowments as should insure systematic and continuous research by the professors as a part of the new university system.

Endowments for the same object, and operating in the same line, might also take a different form, viz. the endowment of several professorial fellowships, each, say, of 1000 dols. annual income; to be controlled and awarded by some independent scientific body (such as this alliance might afford) for distinction in active scientific investigations, either within the country or within the State. I know of no more quickening impulse to original scientific research than such as would be given to it by those means.

How backward we have been in this country, through the lack of proper endowments, in making use of the best existing opportunities for research, may be illustrated by a single instance. Some twenty years ago a school was established at Naples for the prosecution of marine biological research. It is most thoroughly equipped, and, being a general resort, is the most advantageous for study in the world. It is maintained by a charge of 500 dols. per year upon each table occupied, each occupant being entitled to all the advantages of the institution. Of these tables, the German States for several years have taken thirteen; Italy, eight; Austria, Russia, Spain, and England, each three; Switzerland, Belgium and Holland, each one; the United States, until 1891, none, except one table supported by Williams College for two years, and one by the University of Pennsylvania for one year. Prior to that time about fifteen other American students in all had obtained places at the tables taken and paid for by other nations. In 1890 this arrangement was prohibited by the administration of the institution;

and the right to a table in 1891, was secured to Americans, only through the private benefaction of Major Alex. Henry Davis, of Syracuse. For the year 1892 the use of a table has been secured through a subscription started by the American Association for the Advancement of Science, toward which the Association itself granted out of its scanty funds 100 dols. and was the means, I believe, of procuring the rest.[1]

We have not, however, been wholly without some such means of study in this country through the marine biological laboratories established some years ago at Newport and at Wood's Holl, by Prof. Alex. Agassiz. The former has been now enlarged so as to accommodate eight advanced students, besides the professor and his assistant.[2] The Johns Hopkins University also has supplied some opportunities of this kind by its summer school, formerly at Beaufort; later, at Jamaica; but at present, as I understand, it is without any permanent location.

Our neighbour, the Brooklyn Institute, has organised similar investigations, on a minor scale, during the summer months at different places on Long Island. But what is needed for the most effective work is suitable endowments for professors and advanced students, in connection with an adequate biological laboratory, such as the Newport one enlarged might afford, equal in means and equipment to that at Naples, or at least to that recently completed, largely through private enterprise, at Plymouth, England.[3]

(To be continued.)

SCIENTIFIC SERIALS.

Bulletin de l'Académie Royale de Belgique, Nos. 9 and 10.—On the conversion of black mercuric sulphide into red sulphide, and on the density and specific heat of these bodies, by W. Spring. As a general rule, if a body is capable of existing in two allotropic states with different densities, it is possible to convert the lighter into the heavier kind by compressing it to the higher density, the pressure depending upon its compressibility. Sometimes this conversion is only possible above a certain "critical temperature." In the case of the sulphide of mercury the conversion of the black into the red variety (vermilion) involves a compression of 9 per cent., and would require a pressure of 35,000 atmospheres, which is not at present attainable. But M. Spring has succeeded in obtaining a new form of black HgS which only requires 2500 atmospheres. It is obtained by sublimation of ordinary black HgS in an atmosphere of nitrogen or CO_2. Its density is 8·0395, while that of vermilion is 8·1587, and of ordinary black HgS 7·6242. A curious side result of the investigation is that the black sulphide hitherto known, after being made to expand by heat and then cooled, takes about a day to return to its original density.—Vapour tension and hygrometric state, by Dr. J. Verschaffelt. A new hygrometer may be based upon the fact that the hygrometric state of the atmosphere may be taken as the ratio of the vapour tension inside a solution to the highest possible vapour tension of water at the same temperature, if the tension inside the solution is equal to that in the atmosphere, *i.e.* when the solution does not evaporate or gather moisture from the air. The ratio mentioned is independent of the temperature, and hence the humidity is simply a function of the concentration of the solution. In practice, Dr. Verschaffelt moistens a weighed piece of blotting-paper with a weighed quantity of a solution of lithium chloride of known concentration, exposes it to the atmosphere, and weighs it again. From the last weight the "equilibrium concentration" may be calculated, and from this the humidity with the aid of Dieterici's data for this salt. The apparatus might be made self-registering.

[1] See *Proceedings American Association A. S.* 1891, vol. xl. p. 449-451.
[2] *Report Harvard College*, 1891, p. 182.
[3] In his address before the American Association for the Advancement of Science, in 1891, President Prescott, referring to this general subject, said: "To nurture investigation in science is the largest opportunity before the American people. Research, systematic and wisely directed, requires good organisation and strong support, the support of many powers. It must have the support of able and persistent men. It needs the conference of workers, and the dissemination of knowledge in societies like this. It wants the interest and the confidence of the public. It asks and will always obtain the constant, helpful use of the press. It requires distinct provision in colleges, and in the institutions of higher education. It ought to be sustained expressly by the Government, both in the several States and under the United States, and sustained on broad and permanent foundations. Still, it needs private benefactions. Research is the growth of years. Let it be the demand of all, and let this call find utterance everywhere."—*Proceedings American Association*, 1891, vol. xl. p. 440.

Bulletin of the American Mathematical Society, vol. i. No. 2. (New York, Macmillan, November, 1894.)—On the problem of the minimum sum of the distances of a point from given points, is the translation, by A. Ziwet, of a paper presented to the Society at its summer meeting (August 15), by Prof. V. Schlegel (pp. 33-52). This frequently discussed problem (see references given by Sturm, *Crelle's Journal*, vol. 97), is considered by the author to offer room for further treatment. He discusses the best method of investigating the question, and in the end treats it by means of the simplest methods of Grassmann's "Ausdehnungslehre." Prof. Cajori collects a number of authorities in confirmation of a statement in his "History of Mathematics" (p. 218), that it is *not* true that the binomial theorem is engraved on Newton's monument in Westminster Abbey. The latest additional authority for his statement is contained in a letter from the present Dean of Westminster, whom Prof. Cajori calls "Dr. Granville"!—The only other matters are the notes and new publications.

SOCIETIES AND ACADEMIES.

CAMBRIDGE.

Philosophical Society, November 26. — Prof. J. J. Thomson, President, in the chair.—On Benham's artificial spectrum, by Prof. G. D. Liveing. Prof. Liveing exhibited one of Benham's "artificial spectrum tops" (see NATURE, November 29, p. 113), and a variety of discs with figures in black disposed on a white ground, and with white figures on a black ground, which, when revolved in a bright light showed remarkable bands of colour of various shades of red, green, and blue. The general result of his observations of these discs was that if a succession of black and white objects were presented to the eye with moderate, but not too great, rapidity, then, when black was followed by white, an impression of a more or less red colour was perceived, while when white was succeeded by black a more or less blue colour was perceived. If the succession of black and white was very rapid the appearance presented to the eye was of a more or less neutral green or drab. The explanation offered by Prof. Liveing was based on the known facts that the impression produced on the retina by a bright object remained for an appreciable time after the light from the object had been cut off, and that the duration of that impression was different for different colours; and on a supposition, which he did not know to have been as yet verified experimentally, that the rapidity with which the eye perceives colours was greater for one end of the spectrum than for the other. From this point of view the explanation of the blue colour seen when white is followed by black would be that the impression of blue on the retina lasts a little longer than that of the other colours; while the red colour seen when white succeeds black is due to the greater rapidity with which the eye perceives red light than that with which it perceives blue. If, however, the alternations of white and black succeed each other with sufficient rapidity, the new impression of a white patch will be produced before that of its predecessor has vanished, and there will be an overlapping of impressions, and the sensation will be that of a mixture of colours, or of a more or less neutral tint. So far as he could test the theory by his own eyes it appeared to him that the residual impression, left when the light from a white object was suddenly cut off, was at first green and faded out through a more or less blue or slate colour.—On a simple test case of Maxwell's law of partition of energy, by Mr. G. H. Bryan.

PARIS.

Academy of Sciences, December 3.—M. Lœwy in the chair.—The reduction of alumina by carbon, by M. Henri Moissan. The author describes the reduction of pure corundum by means of his now well-known electric furnace. Liquid alumina is not reduced by carbon; the reduction only takes place when the vapours of these substances are carried to a very high temperature, metallic aluminium is then produced and partially combines with carbon.—Reply to M. Mayer-Aymar concerning his defence of *Saharien* as a name for the latest geological period, by M. A. Pomel.—A letter from Prof. R. Fresenius was read announcing the formation of a German committee in connection with the Lavoisier monument. The Academy appointed Prof. Fresenius delegate for this work. Prof. G. Hinrichs was similarly appointed delegate for the

United States.—On the identity of the new comet with De Vico's comet, by M. L. Schulhof (see our Astronomical Column, December 6, p. 132).—Observations of the planet B H 1894, discovered by M. Borrelly at Marseilles Observatory, November 19, 1894; by M. Borrelly.—On the distribution of planets between Mars and Jupiter, by M. E. Roger. A mathematical paper in continuation of a paper on the same subject in the previous number.—On quasi alternate permutations, by M. Désiré André.—On the temperature of the electric arc, by M. J. Violle. The conclusion is drawn, from a spectroscopic study of the poles and the arc itself, that the temperature of the arc is generally higher than that of the positive carbon, and that it increases with the electric energy employed.—On the solubility of ozone, by M. l'Abbé Mailfert. At a pressure of 76 mm. water dissolves two-thirds of its volume of ozone at 0° C., at 12° about one-half. The solubility of ozone in water acidified with sulphuric acid is the same as its solubility in pure water up to about 20° C.; more ozone is dissolved by the acid solution above this temperature. The suggestion is made that ozonised water might be employed as a disinfectant and antiseptic.—On the superposition of the optical effects of different asymmetric carbon atoms in the same active molecule, by MM. Ph. A. Guye and M. Gautier. For the determination of this point the authors have used in the present instance amyl valerate. The ester produced by combining inactive amyl alcohol with active valeric acid gives $[\alpha]_D = +1\cdot08°$, the corresponding compound with active amyl alcohol and inactive valeric acid gives $[\alpha]_D = +4\cdot26°$; the ester obtained from active alcohol and active acid gives $[\alpha]_D = +5\cdot32°$, while the sum of the two former is $+5\cdot34°$. Theoretically a better agreement should be obtained by using the racemic in place of the inactive forms; in this case the sum is $5\cdot62°$. The difference is probably due merely to experimental errors.—Experimental researches on the crystallisation point of some organic substances, by M. Raoul Pictet. The crystallisation points of a number of organic substances are given, and the results are embodied in a number of general conclusions confirming previous work.—On the emission of a saccharine liquid by the green parts of the orange-tree, by Dr. M. Büsgen. The author calls attention to the part played by aphides and similar parasites in the production of saccharine liquids from plants, and includes the orange-tree among the cases of this kind.—Osteomyelitis of the inferior maxillary in the kangaroo, by MM. Lannelongue and Achard.—On the action of the toxine from the pyogenous Staphylococcus on the rabbit, and on the secondary infections which it determines, by MM. Mosny and G. Marcano. The toxine does not confer immunity against the attacks of the living microbe.—Action of high pressures on some bacteria, by M. H. Roger. Notable differences were observed between different bacteria in regard to their behaviour under pressure. The virulence of the anthrax bacillus was very much diminished by a pressure of 3000 kgms.—On the disinfection of fœcal matter, by M. H. Vincent. At about 16° C. the disinfection of normal fœcal substances is brought about in twenty-four hours by 6 kgms. of copper sulphate per cubic metre. Eberth's bacillus is destroyed in typhoidal refuse by 5 kgms. per cubic metre, and the cholera bacillus by 3·5 kgms. of copper sulphate per cubic metre after twelve hours contact.—Marine muds and their classification, by M. J. Thoulet.

BERLIN.

Physical Society, November 2.—Prof. du Bois Reymond, President, in the chair.—The President alluded to the death of Prof. Pringsheim, and drew attention to his important researches on the fertilisation of algæ.—Dr. C. H. Wind gave a comprehensive review of the researches carried on by Dutch observers with reference to Kerr's phenomenon. He then discussed Lorentz's theory, and described the elaborate experiments made by Sissingh and Zeeman and by himself, which had yielded results for iron, nickel, and cobalt, which were not quite in accord with the theory. Since the other theories as to this phenomenon, as, for instance, that of Drude, are still less in accord with experimental facts, the speaker had extended Lorentz's theory so as to take into account the results obtained by Sissingh and Zeeman, and to bring the phenomenon of Kerr into relation with that of Hall. This extension of the theory had been accepted by Lorentz, and Dr. Wind is now engaged on the investigation of certain phases of Hall's phenomenon.

CONTENTS.

THURSDAY, DECEMBER 20, 1894.

SIR RICHARD OWEN.

The Life of Richard Owen. By his grandson, the Rev. Richard Owen, M.A. With the scientific portions revised by C. Davies Sherborn. Also an Essay on Owen's Position in Anatomical Science, by the Right Hon. T. H. Huxley, F.R.S. (London: John Murray, 1894.)

THE life of this well-known and eminent anatomist, written by his grandson, the Rev. Richard Owen, has been based on such a large amount of material that "the writer's chief difficulty has been to compress the biography within reasonable limits." While acknowledging that the art of compression is a difficult one, we still must express some disappointment at the way in which it has been carried out in the two volumes of this biography. For over sixty years Owen filled a more or less conspicuous place in the scientific world; in a large measure a self-taught anatomist, he at a very early age became a teacher of anatomy to others, with a wondrous collection of material at his disposal to illustrate his teaching. In these volumes we do not seem to find enough about his evolution as a man of science, and we could, in some measure, have dispensed with many of the trifling details of his every-day life, which have, if any, but a passing interest. In the following sketch we attempt to show but a phase of Owen's character; but, in common with all who had any personal knowledge of him, we do not overlook, nor can we forget, the charm of his domestic and cultured life.

Richard Owen was the younger son of Richard Owen, of Fulmer Place, Bucks; he was born at Lancaster on July 20, 1804. His mother was of a Huguenot family of the name of Parrin, who came from Provence at the time of the revocation of the Edict of Nantes. He would seem to have inherited from his father many of his physical characters, his height and sturdy frame; while from his mother came his fondness for music, and a certain refinement and courtier-like style of manner which were of some value to him in after-life. Apparently his mental training began early, for we find his father writing from St. Kitt's to his mother, "that he was glad to know James (the elder brother) and Richard came on so well with their studies, and were so attentive," at a date when Richard could not have been more than three years and a half old. When six years old he was sent to the Lancaster Grammar School, to join his elder brother, a school that will be always associated with the name of Whewell, the great Master of Trinity, Cambridge, who received here his early education. Soon after he had left school, we find him apprenticed to Mr. Leonard Dickson, of Lancaster, surgeon and apothecary, and on his death, in 1822, he was transferred to Surgeon Seed, of the Royal Navy; and finally, on Mr. Seed being called upon by the Service, he was committed to the care of Mr. J. S. Harrison. Matriculating at Edinburgh University in October, 1824, he seems to have attended one winter, and possibly a summer, course of lectures. In 1825 he was in London, attending lectures at St. Bartholomew's Hospital School, and became prosector for Dr. Abernethy. On August 18, 1826, he was admitted a member of the Royal College of Surgeons, London.

To the medical student of the present day, compelled to attend a five years' course of lectures and demonstrations, and to pass several examinations, there will seem something enviable in the apparent ease with which Richard Owen obtained his qualification; there was an incomplete apprenticeship at Lancaster, perhaps a year's course of lectures at Edinburgh, and another year, about which we have few details, at St. Bartholomew's, and then he set up as a medical practitioner, and gradually secured a small practice among the lawyers at Lincoln's Inn Fields. To those, however, who try to read under the lines, it will be evident that the abilities and industry of Owen, about which his mother so proudly writes, must have been of no common order. Up in that old tower at Lancaster—"Hadrian's Tower, it was called"—after the first spasm of fright, the particulars of which are so graphically told us by the Professor himself, the youth of sixteen must have carried on his anatomical investigations to such a purpose that we find him, on his visit to Edinburgh, not only able to detect the defects of the teaching of anatomy of Prof. Monro (*tertius*), but able also to attract the notice of John Barclay, and finally, on his visit to London, able to act as prosector to Abernethy. We would have welcomed more information as to how Owen became an anatomist. Was his worthy master at Lancaster, who could learnedly descant on certain pathological conditions, an anatomist, or did the "elder fellow pupil" about whom he writes (who was he?) help him in his studies? Probably we will never know, and yet a knowledge of his doings during these few early years of study would have helped us to an understanding of the man.

In 1827, through the influence of Abernethy, who at the time was President of the College of Surgeons, Owen was appointed Assistant Curator of the College Museum, under William Clift, and he at once proceeded to arrange the collections and to write the descriptive catalogues, the first three parts of which were published in the course of 1830. Before the end of 1827 he was engaged to be married to Miss Clift, and after an eight years' courtship they were married in 1835. William Home Clift had died from an accident in September 1832, and Owen's place at the College then became a permanent one. In 1836 he was appointed Hunterian Professor, and on the retirement of Sir Charles Bell (in the early part of 1837) from the Professorship of Anatomy and Physiology in the College, Owen was elected to the vacant chair. For these latter statements we follow the text before us; but is it not possible that there is some slight confusion here? Up to about the period when Sir Charles Bell resigned the Professorship of Anatomy, the lectures bearing on the Hunterian collections were supposed to have been given in part by the Professor of Anatomy and in part by the Professor of Surgery; but, by a special arrangement, these lectures, twenty-four in number, were, after 1837, to be delivered by Owen, as Hunterian Professor, and "the awful first lecture" was given on May 2, 1837.

For the next twenty years of Owen's life the scene was for the most part laid in Lincoln's Inn Fields.

"'Mr. Owen' was put up on our door-plate to-day. Looks most imposing," records Mrs. Owen, under the date of July 22, 1836, and it was in June 1856 that he entered upon his duties as Superintendent of the Natural History Department of the British Museum. These twenty years were, perhaps, the fullest of Owen's life. The boy who had begun his anatomical studies in Lancaster at sixteen years of age, was, some sixteen years afterwards Hunterian Professor, lecturing before brilliant audiences of grown-up men, and with material to lecture about such as has seldom fallen to the lot of any other man. Numerous were the works published during these years, and numerous were the honours conferred on him. Fully detailed lists of both, occupying many pages, will be found at the close of volume ii. The time was not all spent in tiresome work; Owen's social qualities were of a well-developed order. We are permitted, by his wife's records of their daily lives, to know of days and evenings spent in gay and festive scenes.

In chapter ix. we have a fuller account than, we think, has to this been published about the daring thoughts that were at one time in Owen's mind (1846) about the zoological collections of the British Museum. He calls them "speculations on a concentration of all zoological illustrations—living, dead, exterior, and anatomical—in one great connected establishment"; but, failing such a realisation, he would be satisfied if "all the recent and fossil zoology of the British Museum would come to this (College of Surgeons). The mineralogy would naturally be transferred to the Government Museum of Economic Geology," and "the British Museum would then be left free for the full extension of the departments which concern intellectual man." The last sentence was unfortunately expressed; and within ten years, Owen's ideas—possibly affected by lapse of time and change of scene—had vastly changed. He thought, in 1846, Lincoln's Inn Fields as central a position as Great Russell Street; afterwards, in 1856, though he liked the position in Great Russell Street well, yet for the sake of space he went out into the country. Perhaps, in taking note of this episode, we ought also mention that in 1848 he strongly urged on his friend, Dean Buckland, the importance of the great collection of shells, made by Hugh Cuming, being purchased for the British Museum.

At the close of the first volume there is an interesting letter, dated July 17, 1854, from Charles Darwin, which we do not remember to have seen before. He thanks Owen for his kind appreciation of his work on the Cirripedia. "I got so frightened at the thoughts of all the seaside species, that I have not illustrated and given in detail nearly enough my anatomical work, which is the only part of the work which has really interested me. I find the mere systematic part infinitely tedious. I can, however, honestly state that all I have said on the males of Ibla and Scalpellum is the result of the most careful and repeated observation. If I am ever proved wrong in it I shall be surprised."

On May 26, 1856, Owen was appointed Superintendent of the Natural History Department of the British Museum, and he entered on his duties on June 8 following. We presume that he resigned his position at the College of Surgeons at the end of May, as the letter of the Secretary of the College, forwarding the regrets of the Council, is dated June 12, 1856. Lord Macaulay's letter to the Marquis of Lansdowne, urging that the post should be made for Owen, was written in February 1856; so that the one scene of labour was exchanged for the other almost with the rapidity of a transformation scene, and before the end of June, Owen was examining the "two collections of Mr. Hawkins—those of Dr. Mantell and Mr. Koch"—in the British Museum, which in 1846 he had believed to be so much out of place there. For the next twenty-seven years the interests of the wonderful collection were always very dear to him, and no difficulties, no rebuffs, stopped him from carrying out his plans about them to their uttermost.

Chapter ii. of vol. ii. is devoted to the history of Owen's connection with the British Museum of Natural History at South Kensington. This account "is given as nearly as possible in his own words, the substance being taken from his address to the British Association at York in 1881." It would have been well if this chapter had been revised by some one with a personal knowledge of the state of things existing in the Natural History Department of the British Museum prior to Owen's appointment, or, failing this, of some one up to the traditions of the place; for though, undeniably, space was sadly wanted for the proper display of the specimens, this department, as a department, was scarcely "the most neglected branch of the institution," nor could the condition of affairs be described as "chaos." However, in February 1859, Owen submitted his views in a report to the Trustees, asking for space to display the existing specimens and those that might be expected to come for a generation. Organised and crystallised forms, all were to be now included. This report, with plans, was presented to Parliament by the Trustees; the space demanded required the removal of the collections from Bloomsbury, the time had not come for so great a change, and Mr. Gregory, afterwards Sir William Gregory, here referred to as an "Irish Member," asked for a Committee of Inquiry, which, after a pretty vigorous debate on July 22, 1861, was granted. In May 1862 there was a second stormy debate in the House of Commons, led by Lord Beaconsfield, and the Government were refused leave, by a large majority, to bring in a Bill for the removal of portions of the Trustees' collections in the British Museum. Things, however, changed in 1863; Sir William Gregory had been made Governor of Ceylon (it is difficult to see what effect this could have had on the matter), and in June of that year leave was obtained by a majority of 132 to purchase five acres for the required Natural History building. Between 1880 and 1883 Owen was engaged in superintending the removal of the specimens from Bloomsbury to South Kensington, and at the close of the latter year he retired from his post, the realisation of his idea being attained.

When Owen gave up the charge of the Museum of the College of Surgeons, he also surrendered the Hunterian Chair; he was thus enabled to accept the Lecturership on Palæontology at the Royal School of Mines, in 1857. He gave his first lecture on February 26, concluding the course on April 2. Mrs. Owen notes in her diary, Richard's "design has been clear throughout in these lectures—to show the power of God in his creation." Towards the end of the same year he was appointed Fullerian Professor of Physiology at the Royal Institution, so that there was no relaxation in lecturing work during these years. Owen was President of the British Association at its meeting at Leeds in 1857. We also get a glimpse of him at Aberdeen in 1859, but can find no trace in these volumes of his presence at the Oxford or Cambridge meetings of 1860 and 1862; indeed, even when noticing the publication of the memoir on the Aye-Aye in 1863, no reference is made to the remarkable paper read at the Cambridge meeting on the characters of this mammal as a test of the Lamarckian and Darwinian hypotheses of the transmutation and origin of species, nor is there any allusion to the "two pitched battles about the origin of species at Oxford," nor to Charles Kingsley's well-meant little squib, published during the Cambridge meeting by Macmillan and Co., "On the great Hippocampus Question."

Mrs. Owen, after a married life of nearly forty years, died in May 1873. In 1875 Owen refers to his daily task work becoming tiresome, as well it might to a man past seventy, but several important memoirs were published by him between this year and 1885, and in 1881 he delivered a long address to the Biological Section of the British Association at York, on the new Natural History Museum; this was almost his last public address, and it was delivered with a force and power that reminded his hearers of his early days. On January 5, 1884, Owen was, on his retirement from the post of Superintendent of the British Museum, gazetted a K.C.B. He was present at a meeting of the Linnean Society, at Burlington House, in May 1888, "to receive a gold medal." The medal thus alluded to was one of two struck in commemoration of the centenary of the Linnean Society; one medal was to be given to a botanist, and one to a zoologist. The botanist on this occasion was Sir Joseph Dalton Hooker. Up to the close of 1889 he was occasionally seen at the Athenæum. Early in 1890 he had a slight paralytic seizure, from which he never entirely recovered. In his well-known library, when able to be out of bed, he would sometimes sit for hours looking out wistfully at the view over the park, and on the morning of December 16, 1892, the end quite peacefully came.

As to Owen's position as a writer on anatomical science, we have no occasion to enter, for what we conceive to be by far the most interesting portion of these two volumes is a criticism, in the true sense of this word, thereof so straightforward, searching, and honest as to leave nothing further to be desired. We should like to have transferred the greater part of this analysis by Prof. Huxley of the work done by Owen to our pages. He doubts "if in the long annals of anatomy more is to be placed to the credit of any single worker" than to Owen, and his is "work some of which occupies a unique position, if one considers, not merely its general high standard of excellence, but the way in which so many of the memoirs have opened up new regions of investigation."

As to the judgment passed on the speculative side of Owen's work, will not all now deplore that so much tireless industry, great capacity, and extensive learning were spent on themes profiting so little as the archetype of the vertebrate skeleton and the nature of limbs? Perhaps it may seem to some that Prof. Huxley has devoted too much space to Owen's speculative writings, but, as he says:

"Obvious as are the merits of Owen's anatomical and palæontological work to every expert, it is necessary to be an expert to discern them; and endless pages of analysis of his memoirs would not have made the general reader any wiser than he was at first. On the other hand, the nature of the broad problems of the 'Archetype' and of 'Parthenogenesis' may easily be stated in such a way as to be generally intelligible; while from Goethe to Zola, poets and novelists have made them interesting to the public. I have therefore permitted myself to dwell upon these topics at some length; but the reader must bear in mind that whatever view is taken of Sir Richard Owen's speculations on these subjects, his claims to a high place among those who have made great and permanently valuable contributions to knowledge remain unassailable."

Several interesting portraits of Owen, taken at different periods of his life, form part of the illustrations of these volumes. There are also sketches of the Gateway, Lancaster Castle, and of Sheen Lodge, in Richmond Park.

ELECTROMAGNETIC THEORY.

Electromagnetic Theory. By Oliver Heaviside, F.R.S. Vol. I. (London: The Electrician Printing and Publishing Company, Limited, 1893.)

THE basis of Mr. Heaviside's treatise is the interlinked magnetic and electric circuits. This is taken from Maxwell, but it is much more fully developed, and the analogy between the electric and magnetic circuits is followed out with great care, and is insisted upon at every turn. That you can have a conductor charged electrically, while you cannot have a single magnetic pole, destroys the perfection of the analogy but little. There is a more serious hiatus in the absence of the magnetic analogue to an electric conductor. Mr. Heaviside, however, completes the analogy by imagining such things as magnetic conductors and magnetic currents. The magnetic displacement and convection currents of course exist, but magnetic conduction current, with its corresponding magnetic conductivity, is a most useful notion. The ideas of the magnetic current must not be confused with the unscientific notions of magnetomotive force and magnetic resistance, which are supposed to bring electromagnetism within the intellectual reach of the benighted practical man. At first Mr. Heaviside uses the hypothetical magnetic current as a means of giving his readers a thorough grasp of the interlinked circuits, and of completing the analogy between them. Later, however, in dealing with submarine messages, he shows that magnetic conductivity outside the wires, which is easy to treat mathematically, would have the same effect on the messages as electric resistance in the cable itself, which would be more difficult.

As Mr. Heaviside's first volume has been already reviewed in the *Electrician* and *Philosophical Magazine* by Profs. Fitzgerald and Minchin, and as the work is so full and so suggestive that a review might be longer than the book, this notice will deal mainly with matters not already fully discussed, though of course there will be some overlapping.

It is almost needless to say that Mr. Heaviside does not believe in action at a distance, that he regards energy as being continuous in space, and as moving as matter, and that he treats ether as an entity, and not as a working hypothesis. By the way, in discussing ether, as to whether it is stationary or not, stationary is generally taken to mean relatively to the earth which is honoured with our existence, or at least with regard to the sun which is to give us light. But if motion is considered with reference to infinite distances, the chances are that the ether moves past us at a speed in comparison with which v is infinitesimal. Mr. Heaviside hopes that in the future the young will be trained up to believe in ether as a thing, and will therefore believe in it; but this would be a sort of religion rather than knowledge. No one doubts that electrical disturbances are propagated at a finite speed, and matter, with its inconvenient properties removed or altered, provides a convenient working hypothesis; but to talk of the inconceivable as existing, is using words to which no concepts belong. As most people agree with Mr. Heaviside on these matters, however, it may be as well to say no more in a review. Dealing with the medium, or rather its states, Mr. Heaviside gets rid of the potential treatment. To him induction and its change is of primary importance, and potential is a mere derivative of it. The idea of induction as the essential and potential as derived is less common with the academical than the practical electrician, who also uses the notion of lines of induction.

This treatise is remarkable, among other things, in beginning almost at once with the propagation of disturbances at the speed of light. The author hopes that text-books on light will soon discuss electricity at the beginning instead of at the end. He certainly sets a good example by beginning a book on electromagnetism with the propagation of disturbances in time. By the way, he regards chemistry as an unmathematical science; it is to be hoped chemistry books will soon begin with thermodynamics and electricity, so as to lay an engineering foundation for the study of chemical action.

Mr. Heaviside is, as is well known, a determined opponent of the use of quaternions in physics, and an equally strong advocate of the use of vectors; and a long chapter is devoted to the "Elements of Vectorial Analysis," taking more than a third of the book. In quaternions, vector products have a part at right angles to both the vectors; the ideas thus fitted electromagnetism, and Maxwell availed himself of the conveniences of quaternion notation, and, to some extent, of quaternion ideas. The relations between vectors in quaternions are purely conventional, while in electricity they are physical in one sense, though in another they may be due to conventionalities of definition. The idea of the direction of a current flowing along in a wire was derived from the flow of water in a pipe, and it is possible that we might have so defined electrical and magnetic quantities, and so thought of them, that nothing corresponding to vector products or quotients came in when passing from one to the other of the electric and magnetic systems. Mr. Heaviside objects altogether to quaternions in physics, but does not differentiate clearly between vector and quaternion analysis, and professes that he does not or cannot understand quaternions. It is not likely he cannot. Perhaps he won't. One difficulty, in the way of students at least, is due to writers on quaternions defining something that is not adding as addition, and something that is not multiplying as multiplication, and to their removing the operand and treating the operator as a quantity. This leads to $S\alpha\beta$ being negative, to the square of a vector being negative, and to the reciprocal of a vector being taken in the opposite direction. When an eminent scientific writer recently found, by dividing the value of dy/dx by y that d/dx was equal to 628, some wrongly thought he did not understand the principles of the calculus; but he was only doing in figures what is done in letters in many branches of mathematics. Mr. Heaviside starts off with a definition of the "product" of two vectors. The scalar part is positive, and the vector part is as in quaternions, but there is no idea of the multiplier rotating the multiplicand, though he gives no reason why the multiplicand need not be looked upon as turned through a right angle. It may be asked how Mr. Heaviside avoids quaternions. Using the word in one of its many senses as the operator necessary to change a vector into another, he avoids the difficulty, for the present, by not dividing. Surely if vectors are to be multiplied they must also be divided. If we have the induction and current at an angle, we can find the force; is it not as reasonable to find the induction or current if the force and one of them is given? Perhaps Mr. Heaviside may devise a new quotient or operator which will do this. If $\alpha\beta = \gamma$ we might expect that $\gamma/\beta = \alpha$. This is not so in quaternions, because the scalar part of $\alpha\beta$ is lost, and the quaternion γ/β gives no scalar part. To recover α there might be a term $S\alpha\beta/\beta$. Perhaps Mr. Heaviside will give his own ideas about division in his next volume. Meanwhile, though he avoids the ideas of turning, every vector multiplier is just as much a quaternion as any in Hamilton or Tait, as far as the versor is concerned. A quaternion, though sometimes called an operator, is really two operators. Mr. Heaviside admits quaternions can be developed from his definitions. He also finds it difficult to think of energy disappearing in one place and appearing elsewhere without passing through intermediate space; surely then he can look upon a vector disappearing and reappearing in a new direction, and of a new length, as having passed through intermediate positions and lengths. He then gets the idea of roots of quaternions, $\sqrt{-1}$, and so on, without complicating vector analysis, and has a system which will do all his vector algebra well, which makes sense of imaginaries and exponential values of sines and cosines, which does not involve the study of new symbols or ideas, and which is already worked out: in short, quaternions. He finds difficulty in knowing when a vector is a vector, and when a quaternion. The answer is: it is a vector when it is a quantity, and the versor of a quaternion when it is an operator. There would be no difficulty if people did not confuse an operator with the quantity that specifies it. Confusion, which is common to Mr. Heaviside's vector algebra, may come in between the scalar and vector part of the product of two vectors. He continually falls back on cartesians, and his vector work is apt to degenerate into cartesian shorthand. The object of a calculus is not to save printing, and it is no advantage to have an expression condensed into two or three symbols if you have to think it out at length to understand it. Shorthand is not necessarily short-thought, especially if it also involves writing operators as quantities. It is possible to know the meaning of

$$\left(\mu\rho - \frac{\nabla^2}{cp}\right) \mathrm{H} \text{ where } \frac{1}{p} \text{ is } \frac{dt}{d},$$

it is also possible to know what is meant by "Boyle was the father of chemistry, and brother to the Earl of Cork." It might be suggested that if Mr. Heaviside wants to make either vector analysis or quaternions simple to physicists, he should avoid the confusion between operators and quantities, and between operation generally and multiplication in particular; or else write an introductory calculus of functions showing where such liberties can be taken with impunity.

Mr. Heaviside has a rooted aversion to 4π. This factor came into the system of units from statics, as the mathematical treatment of electricity was much the same. Mr. Heaviside employs a medium treatment, and thinks that 4π should, therefore, disappear. He thinks that Maxwell and other mathematicians did not know how 4π came about, and thought it was a physical necessity. With his treatment it is an advantage to remove the 4π from its usual place; but it only appears in the denominator elsewhere. It is like the eruption due to a disease: suppress it, and it appears elsewhere. The unsavoury metaphor is not ours. The disease is the area of a unit sphere being 4π. Until Mr. Heaviside can cure that, he cannot really eliminate 4π. He whitewashes 4π whenever it appears in his book, saying that it is not the B.A. 4π of amazing irrationality. When a man refers to his own ideas as alone rational, or based on common-sense, or well-known facts, he is generally wrong.

Mr. Heaviside is, as is well known, a prolific inventor of new terms. He says he hates grammar; he has also a murderous hatred of the Queen's English when inventing terms such as "leakance," "reactance," and "potted." Generally speaking, a writer has no business to insist that his reader shall study a new terminology; but when any one of Mr. Heaviside's reputation invents names which are euphonious and good, they become parts of our language, and we must thank him, especially when his terms are suggestive and systematic. The example is bad though. The English language is capable of improvement; but if every writer is to alter it to suit his ideas, it will not improve. It is a matter of taste which terms should be adopted; many object to voltage and gaussage as unsystematic where ampereage, farradage, &c., are not used. Voltage was originally used to denote the pressure for which lamps, dynamos, &c., were designed by the maker, whatever they were run at. Pressure belongs to the same set of ideas as current, capacity, resistance, and quantity; and if they are used, should also be employed. It is, however, a matter of taste only.

The style is that of Whitman, except that Mr. Heaviside is not affected, and has something to say. The similarity is also noted in the *Philosophical Magazine*. Every line of the book is important, and it is full of interesting digressions on all sorts of subjects. Though the converse may not be true, all clever men have a sense of humour, and it is therefore a pity that scientific writers emulate the ponderous dryness of the theologian. Mr. Heaviside's work bristles with humour of a type which he has invented.

It is generally assumed that a review should be written by a man who could have written the book himself. In the case of a writer of Mr. Heaviside's calibre there is difficulty in getting such reviewers. The real object of a book is, however, to teach not those who know the contents already, but the student, and it may therefore be an advantage to review a book from the student's point of view. This review must, therefore, be taken as from that point of view; that is, as written by a reader who has not devoted a large enough portion of his time to the study of mathematics or mathematical physics to be more than a student of them.

J. SWINBURNE.

RECENT PSYCHOLOGY.

Lectures on Human and Animal Psychology. By Wilhelm Wundt. Translated by J. E. Creighton and E. B. Titchener. Pp. x. 454. (London: Swan Sonnenschein and Co., 1894.)

Grundriss der Psychologie. Von Oswald Külpe. Pp. viii. 478. (Leipzig: W. Engelmann, 1893.)

Introduction to Comparative Psychology. By C. Lloyd Morgan. Pp. xiv. 382. (London: Walter Scott, 1894.)

Psychology for Teachers. By C. Lloyd Morgan. Pp. x. 251. (London: Edward Arnold, 1894.)

Primer of Psychology. By George Trumbull Ladd. Pp. xv. 224. (London: Longmans, Green, and Co., 1894.)

THE translation of Prof. Wundt's well-known lectures is taken from the second revised German edition which appeared in 1892, and is therefore well up to date. It is the first work of the author to appear in English, and the choice made by the translators is a good one; while the book will give to those specially interested in psychology a general sketch of the author's views. Its popular and lucid form will appeal to a wider circle of readers who would hardly care to digest the details and technicalities of the "Grundzüge der physiologischen Psychologie."

The greater part of the book is devoted to human Psychology, especially in its physiological and experimental aspects, and there are several interesting chapters on animal psychology, and a short account of the author's views on hypnotic conditions. Prof. Wundt's own opinions are stated rather more dogmatically than is altogether suitable for an elementary book in a science like psychology; thus, in dealing with intensity of sensation, the validity of the logarithmic formula is very positively enunciated, and it is somewhat surprising to find, on p. 306, that indirect association of ideas is "easily demonstrated," when several investigators, one recently in Prof. Wundt's own laboratory, have failed to find any evidence of such a mode of association.

The translation has been very well done, and especial care has evidently been devoted to the rendering of the German psychological terms. The translators have very freely used the term "to sense" as a verb corresponding to sensation, and as the equivalent of "empfinden." This American innovation, which has already been advocated by Dr. Titchener, is also used by Prof. Lloyd Morgan in his two books, and it must be acknowledged that there is decided need of some such term.

Dr. Külpe is chief assistant to Prof. Wundt at the Leipzig Institute, and his experience in teaching and in directing investigation must have contributed largely to make his book what it is—one of the best existing expositions of experimental psychology. The general teaching follows that of Wundt, but there is much that is novel in matter and arrangement. Physiological details and the technique of experimental methods are omitted or treated very briefly, but the principles of the methods are fully discussed. Dr. Külpe's book will probably be largely used as a text-book for advanced students.

Prof. Lloyd Morgan's two books, to a certain extent, cover the same ground. Each is an exposition of general psychological principles to serve as guides, in the one case, to the scientific study of the animal mind; in the other, to the practical study of the child's mind. Both books are characterised by the sound common sense with which the author treats his problems.

The views held on the nature of the animal mind are very similar to those of Wundt. Both agree that in studying animal psychology the scientific method is to explain actions by the simplest possible mental processes, and this method has led both to similar conclusions, although expressed in somewhat different language. Wundt refers all intelligent acts of animals to simple associations, to the exclusion of any higher apperceptive process; while Prof. Morgan explains such acts by simple sense experience, and doubts, though he does not deny, the existence of any true reasoning or reflective process. A point justly insisted on by Prof. Morgan is that observation of an apparently rational action in an animal is of little value without knowledge of the process by which the action has been developed; "in zoological psychology we have got beyond the anecdotal stage; we have reached the stage of experimental investigation."

The book for teachers is very interesting, and contains much that should be of practical value. It is noteworthy that the appreciative preface, with its ample recognition of the part that a knowledge of psychology should take in the equipment of the teacher, is written by Dr. Fitch, late one of H.M. Chief Inspectors of Training Colleges.

Prof. Ladd has attempted a very difficult task in writing a primer of psychology suited for the young. His book is often simple and clear; it is to be feared, however, that youthful readers will find much of it beyond their capacity. The author has, at any rate, avoided the fault of being too dogmatic.

OUR BOOK SHELF.

Radiant Suns. By Agnes Giberne. (London: Seeley and Co., 1895.)

IN this sequel to a former work, the reader is taken by easy stages into the domain of spectroscopic astronomy and the evolution of worlds. Though following some astronomers who ought to know better, the authoress takes the unphilosophical view that the whole process of stellar evolution is one of cooling; and this is the more difficult to understand, as she is evidently not unfamiliar with the fact that a condensing body may actually be getting hotter (p. 307). While strongly advocating the value of hypotheses as aids to investigation, she is inconsistent enough to make contemptuous reference to the "half-fledged" theories of "scientists of a lower order" (p. 240); her qualifications for making such distinctions are not very clear to us, but her opinions seem to depend to some extent on personal bias, since special prominence is given to the views and work of one observer.

A preface is contributed by Mrs. Huggins, who is careful to disclaim responsibility in matters of opinion, and laments that the masses of men overlook the fact that "the investigator, absorbed in pursuits far removed from those of ordinary life, is also a toiling worker, and a worker of the highest order."

The illustrations are admirable and quite up to date. It would be worth while, however, to revise the coloured plate of stellar spectra, so that the spectrum of Vega would not be robbed of its strongest characteristic—the lines of hydrogen.

We believe that the book will succeed in awakening a desire for further knowledge in the minds of thoughtful readers; and if so, it will serve a useful purpose.

Album von Papúa-Typen. Von A. B. Meyer and R. Parkinson. (Dresden: Stengel und Markert, 1894.)

TO ethnologists, the Papuan race is one of the most interesting in the world. Whether the Papuan represents a distinct type of mankind or not is doubted by some observers, though the balance of evidence is in favour of that conclusion. This splendid collection of fifty-four plates reproduced from photographs, and representing about six hundred portraits of individuals, should be of great assistance in studying the similarities and differences between the typical Papuan, and the natives of southern and eastern New Guinea. The photographs illustrate the natives of New Britain, the Duke of York Islands, New Ireland, Admiralty Islands, Solomon Islands, German New Guinea, and Dutch New Guinea. They represent the people as they are ordinarily seen, and also decorated with the strange costumes assumed at feasts. Particularly striking are the pictures of natives of New Britain adorned for one of their Dukduk dances, and of the ingenious basket-work traps used by the fishermen. Ethnology will benefit by the publication of this collection of really excellent pictures.

Farm Vermin, Helpful and Harmful. By various Writers. Edited by John Watson, F.L.S. Pp. 85. (London: William Rider and Son, Limited, 1894.)

COMPOSITE books are almost always unsatisfactory, the chapters by the various contributors being necessarily unequal in quality and length. We really cannot understand why this little book of eighty pages should not have been written by a single zoologist, instead of the eight who have helped to construct it. The only justification for the patch-work is that each of the writers is more or less an authority upon the subject he describes; but the book is of such an elementary character, that it is difficult to believe that so many minds are necessary for its construction. The contributors are Sir Herbert Maxwell, Mr. O. V. Alpin, Mr. John Cordeaux, Mr. Cecil Warburton, Dr. J. Nisbet, and Mr. C. B. Whitehead. Each tells his tale in his own way, and the editor amplifies the information here and there by means of foot-notes. Farmers will find the book a handy and simple guide, and one which will enable them to know their friends and enemies among the "varmints."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The New Cypress of Nyasaland.

THE interesting account of *Widdringtonia whytei* (NATURE, November 22, pp. 85-87) discovered by Mr. Whyte on the Milanji plateau, suggests a few brief comments.

(1) It is said to extend "the geographical range of the genus hitherto known only from South Africa, Madagascar, and Mauritius into tropical Africa." As far as the latter statement is concerned, this is no doubt true. But the existence of any species of the genus in Madagascar or Mauritius seems to be wanting in sufficient evidence, though repeatedly cited by authorities. Thus Madagascar is given in the geographical distribution for the aggregate genus *Callitris* in Bentham and Hooker, "*Genera Plantarum*," vol. iii. p. 424; Dr. Masters, *Journ. Linn. Soc. Bot.* vol. xxx. p. 17, says "one (*Widdringtonia*) has been discovered in Madagascar"; Mr. Rendle, *Trans. Linn. Soc.* (2nd series) *Bot.* vol. iv. p. 61, speaks of the "South African and Mascarene *Widdringtonia*."

All these statements are based on a species, *Widdringtonia Commersonii*, which was *cultivated* at Réduit, Mauritius, and of which the native country was assumed to be Madagascar, though this has never been confirmed.

In 1806, it is referred to in the "Nouveau Duhamel," vol. iii. p. 10, as *Thuya quadrangularis*, with the following remark: "Habite l'isle de Madagascar; depuis quelques années on le cultive au réduit, jardin de botanique a l'Isle de France."

The Madagascar habitat was apparently purely conjectural. And though the island has of late years been pretty assiduously worked by French, German, and English botanical collectors, no conifer has been detected in it except *Podocarpus*.

In 1833 the development of the myth went a step further. Brongniart cites the species in the *Ann. des Sc. Nat.*, series 1, vol. xxx. p. 190, under the name of *Pachylepis Commersonii*, with the remark: "Hab. in Insula Mauritii in loco dicto Le Réduit (Commerson, 1769)."

Thus it will be seen that, starting as an introduced Madagascar species cultivated in a botanic garden in Mauritius, it finishes with being treated as an undoubted native of that island.

It is, however, to be noted that from "Baker's Flora of Mauritius and the Seychelles" (1877) the *Coniferæ* appear to be entirely absent from the Mascarene Islands.

(2) There is nothing improbable in a *Widdringtonia* occurring in Madagascar. But none has yet been detected with any certainty. It seems not improbable that Commerson's plant was really derived from South Africa. This would seem to be the conclusion at which Carrière arrived in 1867, "Conifères," ed. ii. p. 67:—"Cette prétendue espèce me parait ê re à peine une forme de la précédente." (*W. cupressoides*, one of the two South African species).

(3) The *Coniferæ* for the most part can hardly be regarded as other than a very ancient and a decaying group. Their existing distribution is therefore peculiarly interesting. Bentham and Hooker unite under *Callitris* a number of small genera which practically only differ in the number of their ovule-bearing scales and in their geographical distribution. They divide the genus so reconstituted into four sections, of which two are broadly Australian, two are African. Other instances of parallelism between the Australian and African floras are well known and are full of interest. Of the African sections one is confined to the north, with one species, *Callitris quadrivalvis*, which yields the gum Sandarach of modern commerce, and produced the Thyine wood once so prized by the Romans; the other section, with two species, is confined to the south. The occurrence of a third species on the Milanji highlands is entirely in harmony with what we know of the distribution of plants in Tropical Africa. As has been shown now in numerous cases, a temperate and possibly more ancient flora more or less overlies at elevations where it can exist, the lower lying tropical one, and it forms a series of broken links by which the connection of the temperate flora of Europe and of the Mediterranean basin with that of South Africa, and even of the Madagascar uplands, are at least indicated.

It may be remarked that another coniferous genus, *Podocarpus*, behaves much in the same same way as *Callitris*. Four of the five African species occur at the Cape, and two on Kilima-n'jaro. *Juniperus*, on the other hand, though well represented in Northern Africa, occurs in Abyssinia and the Masai country, but yet does not reach South Africa.

W. T. THISELTON-DYER.

Royal Gardens, Kew, December 10.

The Kinetic Theory of Gases.

I SHOULD like to ask Mr. Culverwell what are the "other considerations" from which we know that in a system of elastic spheres the error law gives the only permanent state.

I will endeavour to extend the proof of the H-theorem which I gave for elastic spheres to a more general, but not the most general, case.

The coordinates of a molecule are x, y, z, defining its position in space, and $q_1 \ldots q_{n-3}$, the momenta are $p_1 \ldots p_n$; and different values of the same variables shall be denoted by PQ and, as the case may require, by accented letters p'P', &c. The number per unit volume of molecules, for which the variables p and q are between assigned limits, is $f\,dq\,dp$, and f is a function of the p's and q's independent of $x\,y\,z$.

The number of pairs for which one molecule has variables P′Q′ between assigned limits, *i.e.* is in the state P′Q′, and the other $p'q'$ between assigned limits, *i.e.* is in the state $p'q'$, is $F'f'a P' dQ' dp' dq'$.

Each molecule has a centre of gravity. It is possible to describe a sphere about that point as centre, such that if the centre of gravity of another molecule be on or beyond that sphere, no appreciable force is exerted between the two molecules. Let a be the least radius of such a sphere. Then when the centre of one molecule is on the sphere of radius a described round the centre of another, an encounter begins or ends between the two molecules.

Now suppose an encounter to take place between a pair of molecules one of which is in the state P′Q′, and the other in the state $p'q'$. As the result of the encounter the variables $P' \ldots q'$ assume new values, but what particular values they shall assume, given $P'Q'p'q'$ before encounter, depends on the two coordinates $\theta'\phi'$ defining the position of the centre of one of the two molecules on the "a" sphere described about the centre of the other at the commencement of the encounter.

Inasmuch as no work is done in moving the centre of one molecule on the surface of this sphere, it is evident that the "sorting demons" can make the result of the encounter anything that they please, *conservatis conservandis*.

Let us suppose that if these spherical coordinates lie between the limits θ' and $\theta' + d\theta'$, ϕ' and $\phi' + d\phi'$, the variables will after encounter lie between the limits $P \ldots P + dP$, &c., that is, the pair will be in the state Pq, and $\theta'\phi'$ will have become $\theta \ldots \theta + d\theta$ and $\phi \ldots \phi + d\phi$.

I will now assume (condition A) that the coordinates $\theta'\phi'$ are taken at haphazard without regard to the variables $P'q'$; if that be so, the chance that, for given $P'q'$ before encounter, the pair of molecules shall be in the $Pq\theta\phi$ state after encounter is $\frac{d\theta' d\phi'}{4\pi}$.

But the number of pairs which now are in the state $P'q'$ is

$$F'f'dP' \ldots dq'$$

And therefore the number which after encounter will be in the state $Pq\theta\phi$, having passed thereto from the state $P'q'$, will be

$$F'f'dP'dQ'dp'dq'\frac{d\theta' d\phi'}{4\pi},$$

which is equal to

$$\frac{1}{4\pi}dPdQdpdqd\theta d\phi \, . \, F'f'.$$

Now let $P' \ldots q'$ be made to pass through all values from which, θ' and ϕ' being suitably chosen, they can assume after encounter the given values $P \ldots P + dP \ldots q \ldots q + dq$. The final values of θ and ϕ will vary, but all possible values of θ and ϕ must appear for some or other of the values through which $P' \ldots q'$ pass, and therefore we shall by this process obtain the whole number of pairs which are in the state $P \ldots q$ after encounter, without restriction of the state which they had before encounter. It will be, namely:

$$dPdQdpdq \cdot \frac{\iint F'f'dP'dQ'dp'dq'}{\iint dP'dQ'dp'dq'}$$

But the number which are in the state $P \ldots q$ now is

$$dPdQdpdqFf.$$

Therefore, as the result of encounters, it is increased by an amount proportional to

$$dPdQdpdq \iint (F'f' - Ff)dP'dQ'dp'dq'.$$

From this point, thanks to the labours of Boltzmann and Watson, the proof is easy, and I need not repeat it, that $\frac{dH}{dt}$ is negative or zero.

I have assumed condition A. I do not say that that is the only assumption that will answer the purpose. But it is sufficient. And it is, I think, the most useful assumption, because the distribution of coordinates assumed to exist is that which would tend to be produced by any disturbances acting on the system from without.

The proof in this form is not open to the objection that by reversing the velocities we can prove two mutually contradictory propositions.

Oh, that now my friend would write a book, and point out with regard to these assumptions what more is necessary, or what less sufficient. S. H. BURBURY.

Lincoln's Inn, December 5.

P.S.—Dr. Larmor describes the reverse motions as the "exceptions which do not disprove the rule." I would apply the maxim *Exceptio probat regulam* in a slightly different sense. They are the exceptions which put the rule to the proof. They compel you to define accurately the limits within which the rule holds. When that has been done for Boltzmann's law (if it has not been done already), it will be time to consider how far the cases which fall within the law are more important than those which fall without it. S. H. B.

December 15.

THE presence of any assumption in Dr. Watson's able proof of Boltzmann's Minimum Theorem might easily be overlooked; but if Mr. Culverwell will apply his test of reversing the motions in each separate stage of the proof, he will unearth the assumption at once. On the top of p. 43 Dr. Watson says:

"And therefore the expression

$$FfdP_1 \ldots dq_{n-1}\, q_n$$

is the number of pairs of molecules, one from each of these sets, passing from the state P, $P+dP \ldots q$, $q+dq$ to the state P', $P'+dP' \ldots q'$, $q'+dq'$ per unit of time, where q_n is put equal to 0 in f."

Now let the motion of every molecule be reversed as Mr. Culverwell suggests. It will be convenient to speak of the two states as the *unaccented* and *accented* states, and we shall thus have the assumption that the expression

$$FfdP_1 \ldots dq_{n-1}\, q_n$$

(which is also equal to

$FfdP_1' \ldots dq'_{n-1}\, q'_n$ but *not* to $F'f'dP_1' \ldots dq'_{n-1}\, q_n'$)

shall represent the number of pairs of molecules passing back *from the accented to the unaccented state*, and this number will depend on F and f, *the frequencies of distribution which the molecules are about to have after the collisions have taken place.*

If this assumption be made we doubtless shall have a case in which H tends to a maximum instead of a minimum, and if Mr. Culverwell endows his molecules with the power of forethought and the prediction regarding their future state necessary to enable them to regulate their movements according to this suppositious law, then Dr. Watson's proof, and indeed any proof, will necessarily fall to the ground. If however the motions of the molecules are allowed to take their own natural course, and nothing special is known about them, the only reasonable assumption to make is that the number of pairs passing from the accented to the unaccented state per unit time is

$$F'f'dP_1' \ldots dq'_{n-1}\, q'_n$$

and this assumption is actually made by Dr. Watson in the next few lines of his proof that H tends to a minimum.

What Mr. Culverwell's objection shows, then, is that it is possible to conceive the molecules of a gas so projected that they would not tend to assume the Boltzmann-Maxwell distribution.

But practically it would be impossible to project the molecules in their reversed motions with sufficient accuracy to enable them to retrace their steps for more than a very few collisions, just as, if we try placing a number of pool balls in a straight line on a billiard table at distances of a foot or two apart, we find it impossible to project the first ball with sufficient accuracy for each ball to strike the next in front all down the line if there are many balls.

The question of the choice of coordinates has been so fully dealt with by Dr. Watson that I need say nothing more. However, if Mr. Culverwell prefers, he may transform from Dr. Watson's $Q_1 \ldots q_n$ to any other variables defining the position of the *pair* of molecules, *provided that he works with the corresponding generalised momenta* instead of $P_1 \ldots p_n$, and he will have no difficulty in choosing one of his *new* variables to be such that it vanishes at an encounter.

I think Lorentz's paper ("Sitzungsberichte der Wiener Akademie," 1887, p. 115) affords the fullest account of the assumptions underlying the proof of the Minimum Theorem.

Cambridge, December 5. G. H. BRYAN.

Science and History.

I SEE by your review of the *National* in the last number of NATURE, p. 162, that Prof. G. W. Prothero, in his "Address on History," takes occasion to notice Buckle's "History of Civilisation." "Buckle," he says, "in illustrating his theory that national character depends largely upon food, attributes the weakness of the Hindoos to an almost exclusive diet of rice. A striking but misleading generalisation, for, as Sir H. Maine has pointed out, the great majority of Hindoos never eat rice at all." Buckle, however, never said anything of the kind; and since no author wrote more clearly than he did, it is evident that the Professor, like many before him, has not taken this extract at first hand.

What Buckle did say was: that rice, millet, or whatever the Hindoos fed on, was grown with little trouble and in abundance; that the climate made clothes superfluous; that living was consequently cheap, and that hence the population increased beyond the demand for labour; labour was ill-rewarded, and the population became practically enslaved. I put the argument very shortly and inadequately, for any one may see it fully set forth in the "History of Civilisation," 1858, vol. i. pp. 63-74.

Sir H. Maine utterly failed to perceive that whatever might have been the food that the Hindoos lived upon, it made no difference to the argument provided that that food was cheap. He was further wrong in his statement that the Hindoos did not feed on rice, as it used to be a far more usual article of diet than in later times; but his worst mistake was to limit the argument to the people of India, who were only one people, out of many, used to illustrate the point.

ALFRED H. HUTH.

London, December 18.

Geometry in Schools.

As a mathematical teacher of long experience, I wish to state that I thoroughly agree with Prof. Henrici that experimental geometry should be taught *antecedently to* and *concurrently with* a rigorous deductive course.

Teachers who have to introduce young students to the study of deductive geometry (*to begin Euclid*, as it is called) are confronted with two difficulties. Their pupils in many cases (1) have never been seriously taught to reason about anything; (2) have no stock of geometrical ideas to reason about. The attempts made in kindergartens to give sound notions of form by means of models, patterns, &c., are excellent as far as they go, but there seems to be great need of a systematic course specially designed to lead gradually up to the study of deductive geometry. The following books will be found useful by teachers who care to give the experimental method a trial: "Paper Folding," by T. Sundara Row (Addison and Co., Madras); "Inventional Geometry," by W. G. Spencer (Williams and Norgate); "Experimental Geometry," by Paul Bert (Cassell and Co.); "Natural Geometry," by A. Mault (Macmillan and Co.); "Geometrical Drawing," by A. J. Pressland (Rivington, Percival, and Co.). To these may be added some older ones, which may occasionally be picked up second-hand: Scott Russell's "Geometry in Modern Life," Dupin's "Mathematics," and "Conversations on Geometry" (Anon.).

Adelaide Square, Bedford. EDWARD M. LANGLEY.

LILIENTHAL'S EXPERIMENTS IN FLYING.

IN a previous article in NATURE (vol. xlix. p. 157) we had occasion to refer to the very interesting experiments which were being carried out by Herr Otto Lilienthal with regard to the possibility of human beings being able to acquire the art of flying through the air, more or less, in the fashion of birds.

These investigations in aerial navigation are conspicuous from all other attempts of the present day, by their great difference in the method of procedure adopted. The principle of Maxim's machine, for instance, is to construct an apparatus to navigate the air by itself, carrying one or more passengers. Every movement of the machine, however, is left to the apparatus itself, and to battle with the difficulty of sustaining its own equilibrium the mechanism must necessarily be most complicated.

Lilienthal depends for the success of his apparatus on himself, trusting to his powers of *instinct* to keep his equilibrium by corresponding movements of his centre of gravity. Man in this case is the main flyer, the apparatus being only an adjunct, and it is from the ability of the former that he expects to obtain positive results. His apparatus is simple, cheap, and easily constructed; these are great points, as experiments can be carried on, even at the expense of the loss of a few machines.

The whole success of aerial flying can be summed up in the word *equilibrium*, and it is here that the difficulty lies. Given a perfectly quiet or very nearly still air, there is no doubt that machines can be constructed so as to soar and travel through the air. This state of atmosphere is very rare; but, on the other hand, there are all sorts of disturbances, currents, and wave-motions which render aerial navigation a far greater difficulty than is usually imagined.

One often envies a bird which, with perfect ease, soars above us; but it must be recollected that it is endowed with a delicate system of nerves which are always on the alert, and answer to any call made on them to sustain equilibrium. These movements are made quite unconsciously, and with the loss of the minimum amount of energy. To construct an apparatus that would accomplish this in an efficient manner would be simply impossible; but there seems no reason why man should not approximate to it to a certain extent by the help of an appropriate framework. With perseverance and many trials he should be able to master at least some of the rudiments, and eventually make short flights.

For this reason Herr Lilienthal's experiments must be looked upon as yet only as first attempts, and consequently as experiments pure and simple, and experience only will show how far they can be successfully brought. Falls must be expected in the preliminary trials until the operator becomes accustomed to the many new conditions which make themselves apparent at every step, before they can be mastered instinctively. Similar difficulties have to be contended with when learning to ride a bicycle. The beginner is at first unable to keep his equilibrium, and so wobbles here and there, with the loss of much power, until he eventually finds himself hugging the earth. This is simply because he is doing something unusual, and is not accustomed to the new conditions. An adept rider, on the other hand, never thinks of the possibility of falling, and quite unconsciously keeps his equilibrium without any exertion or

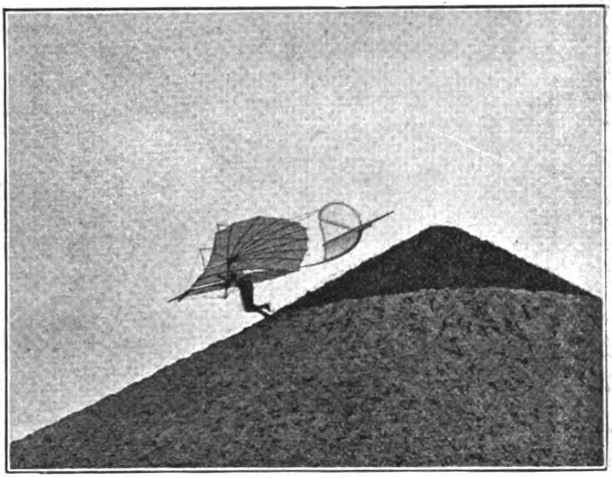

FIG. 1.

loss of power on his part. So it is with this new sailing machine, and it is only by practice that success can be attained.

To commence operations the simplest apparatus must be used, and the easiest steps attempted. This is the way Herr Lilienthal began. In his first experiments, with the help of his wing-shaped framework, he made flights from elevated points in calm weather, the lengths

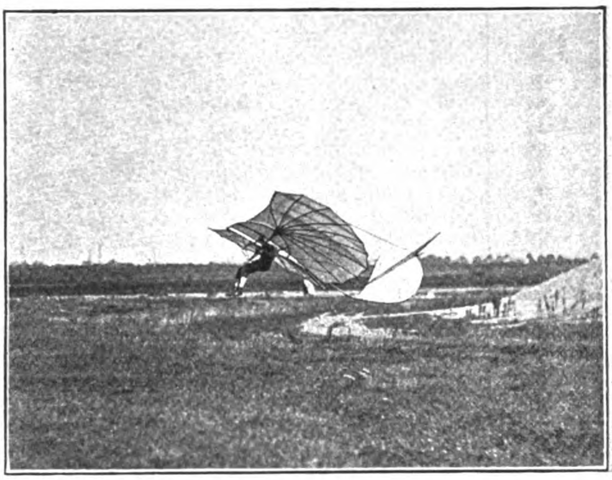

FIG. 2.

of these flights increasing as he gained in experience. Sometimes as many as 500 metres were covered in one bound under satisfactory conditions.

In his more recent experiments he has been making considerable progress in developing this mode of sailing. Two objects have been kept well in mind: the first, to accomplish that method of sailing which is adopted by birds which spend hours in the air at a time without ever flapping their wings; and second, to apply to his apparatus such dynamical means that will enable him, when sailing in a calm atmosphere, to prolong his flights.

To carry out these experiments he has thrown up, in the neighbourhood of Berlin, a large conical mound, fifteen metres in height; this mound he uses as a starting-point for his flights. In Fig. 1 the operator is shown just commencing one of these flights.

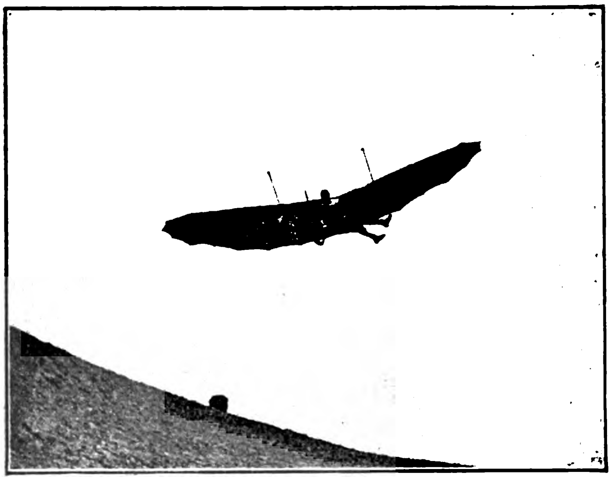

FIG. 3.

With a tight grip of the framework with his hands, he runs quickly down the slope until he has attained a sufficient velocity to raise him and his apparatus off the ground. When such conditions have been obtained, he sails off until he alights again on the earth. Fig. 2 shows him just about to alight. It will be noticed that to come down easily and softly, he puts on the brake by offering to the air a greater expanse of wing, whereby his velocity is at once reduced.

By experience Herr Lilienthal has found that although in quiet weather he can manipulate his craft very easily, in windy weather the operator has to be more careful. The investigations in this direction have, however, been satisfactorily made, and he can now by an adroit movement of his body and that of the apparatus sustain his equilibrium, and sail successfully.

In his article on this subject (*Prometheus*, No. 261, p. 7), from which these references to his new experiments have been taken, he states that sometimes, when a strong wind was blowing, he has been surprised by sudden gusts, which, before he had time to make the necessary movements to sustain his equilibrium, had carried him high up in such a manner as to often take his breath away.

Fig. 3 illustrates the operator receiving such a sudden shock; it will be seen at once that to contend with these new conditions he has had to bring his sail up to the direction of the blast, and to meet it if possible, while at the same time he has altered his whole centre of gravity by a movement of the lower part of his body.

Such movements as these cannot yet be made quite instantaneously, owing to lack of experience; but, as he justly remarks, with more practice he will no doubt be able to make them instinctively, just as the bicycle-rider does.

To attain his second object, that is, to employ some mechanical aid to help him to sustain himself for longer intervals of time in the air, he has constructed a new apparatus, somewhat, but not quite, similar to that up till now used. A good idea of this can be obtained from the accompanying illustration (Fig. 4).

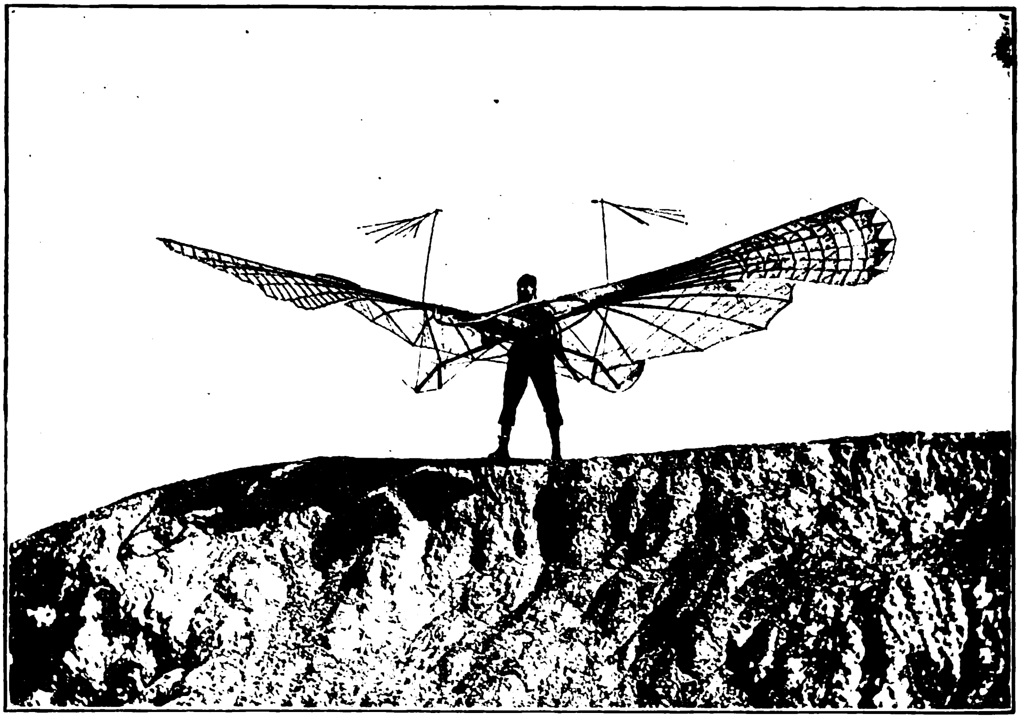

FIG. 4.

A comparison of this *flying* machine with the *sailing* machine in the previous figures will show that the extremities of the wings have been differently constructed, being composed at the ends of a series of feather-like sails. These latter are connected with a small machine, near the operator's body, which is driven by compressed carbonic acid gas; it is set in motion by a simple pressure of the finger. Such an addition has of course increased very considerably the weight and, therefore, the difficulty of handling the apparatus, and as yet it has only been used when the conditions were very suitable, as one serious fall would break up the machine.

Nevertheless the results up to now are very promising, and in calm weather Herr Lilienthal has been able to considerably prolong his flights. When, with the ordinary *sailing* machine, he would have come naturally down to the ground, he has found that an occasional flapping of these wings has helped to sustain him a longer time in the air, and to consequently cover greater distances.

Herr Lilienthal has shown now, that, with the simple sailing machine, flights can be made without any great risk. It would be good for the future progress of this mode of sailing if those interested in it, and who have the time and money, would take it up and pursue it further. What is wanted now is experience, and this can only be obtained by the co-operation of many workers.

PETERS—DENZA—RANYARD.

ASTRONOMICAL science has lost three of its votaries during the present month. Dr. C. F. W. Peters died on December 2, and Father F. Denza, as well as Mr. A. C. Ranyard, passed away on Friday last.

Dr. Carl Friedrich Wilhelm Peters, Director of the Königsberg Observatory, died on December 2, after a protracted illness. He was born on April 16, 1844, at the Pulkowa Observatory, where his father, Prof. C. A. F. Peters, held an appointment under the Russian Government. In 1849 his father was appointed to the Chair of Astronomy at Königsberg, and in 1854 he was made Director of the Altona Observatory, which was afterwards transferred to Kiel. The son studied astronomy and mathematics at Berlin, Kiel, München, and Göttingen, and was placed on the staff of the Hamburg and Altona Observatories. Between 1869 and 1872 he made some valuable pendulum observations, chiefly for the Prussian Government. As Privatdocent at Kiel University he undertook a long series of chronometer tests for the German Navy, in the course of which he proved that they are influenced by changes of humidity as well as by changes of temperature. In 1880, upon the death of his father, he edited the *Astronomische Nachrichten* for a year, after which he was appointed Extraordinary Professor at Kiel University. In 1883 he undertook the direction of the Naval Chronometric Observatory at Kiel, whence he proceeded in 1888 to the directorship at Königsberg, where he terminated a useful and laborious career.

Father F. Denza died at Rome on the 14th inst. from cerebral hæmorrhage. He was well known to the scientific world by his works in astronomy, meteorology, and terrestrial magnetism, and at the time of his death was President of the Italian Meteorological Society, and Director of the Observatory at Moncalieri, which he founded in 1859, as well as of the Vatican Observatory, which was established by the Pope in 1891. It was owing to the untiring energy of Father Denza that the *Corrispondenza Meteorologica Italiana* was established in connection with the Alpine Clubs, and that the results of observations at a large number of stations in the Alps and Apennines have been regularly published in the organ of the Italian Meteorological Society. He was elected an honorary member of the Royal Meteorological Society in 1870.

In astronomy his chief work relates to the observation of meteors. For several years he issued instructions to observers of meteors previous to every important shower, and he published numerous tables and papers on the observations carried on under his guidance, both in *Comptes-rendus* and the *Monthly Notices* of the Royal Astronomical Society. When the Directorship of the Vatican Observatory was taken by Father Denza a very comprehensive programme was drawn up, embracing investigations in meteorology, terrestrial magnetism, geodynamics, and astronomy. Observations in each of these branches of knowledge have increased in number every year since then, and the fourth volume of the *Pubblicazioni* of the Observatory, received by us on the same day as the news of Father Denza's death, is even greater in bulk than any of the previous ones. Father Denza was chiefly instrumental in making the Vatican Observatory one of those co-operating in the production of the photographic star-chart. He devoted his best energies to the advancement of the scheme, and to the progress of astronomical photography. The reports to which reference has been made, contain evidence of his knowledge of what had been done in other astronomical observatories, and of his ability to direct and further the advancement of celestial photography. His services to astronomy have earned for him an honoured place in our memory of the sons of science.

Mr. Ranyard was born in 1845. He was educated at Cambridge University, and was called to the Bar in 1871. He was one of the founders of the London Mathematical Society, of which he was originally joint secretary with Mr. George De Morgan, Prof. Augustus De Morgan being president. He became a Fellow of the Royal Astronomical Society in 1864. In 1870 he was assistant secretary of a joint committee of the Royal Society and the Astronomical Society, which organised the expedition despatched to Sicily, Spain, and Oran to observe the total solar eclipse of December 21. On his return to England he undertook to assist Sir G. B. Airy in the preparation of the report of the observations of the total eclipses both of 1870 and 1860. Ultimately Sir George Airy transferred the work entirely to Mr. Ranyard, and in 1880 the report was published by the Royal Astronomical Society as vol. xli. of its "Memoirs." He observed the total eclipse of July 29, 1878, from Cherry Creek, near Denver, Colorado, and the total eclipse of May, 1882, from Sohag, in Upper Egypt. In addition to papers on the corona and matters connected with physical astronomy, he also published papers on the "Early History of the Achromatic Telescope," and on "Photographic Action." In conjunction with Lord Crawford and Balcarres, he undertook in 1872 a series of experiments on photographic irradiation; and in 1886 he demonstrated by a series of experiments that the intensity of photographic action varies directly as the brightness of the object photographed, and directly as the time of the exposure. The "Old and New Astronomy," designed by Mr. Proctor, was completed in 1892 by Mr. Ranyard, who contributed to it some very important sections on the structure of the stellar universe.

NOTES.

THE newly-discovered gas is to be the subject of a discussion at a meeting of the Royal Society on January 31, when Lord Rayleigh and Prof. Ramsay will present their paper. This will be the first meeting under a resolution of the Council of the Society passed last session, whereby certain meetings, not more than four in number, are to be devoted every year, each to the hearing and consideration of some one important communication, or to the discussion of some important topic.

AT the request of the Ottoman Government, Dr. G. Agamennone, of the Italian Meteorological and Geodynamic Office, will shortly proceed to Constantinople to found there a seismological observatory of the first order. Amongst the instruments to be erected are an Agamennone seismometrograph and a tromometer similar to those in use in the principal Italian observatories. The tromometer will be provided with a photographic recording apparatus, and is specially adapted for registering the long-period pulsations from distant earthquake centres.

DIRECTORS of Botanic Gardens abroad will be glad to know that a list of seeds of hardy herbaceous annual and perennial plants and of hardy trees and shrubs which, for the most part, have ripened at Kew during the year 1894, is given in an appendix, recently issued, to the *Kew Bulletin*. These seeds are not sold to the general public, but are available for exchange with Colonial, Indian, and Foreign Botanic Gardens, as well as with regular correspondents of Kew. No application, except from remote colonial possessions, can be entertained by the Director of the Royal Gardens at Kew after the end of March.

THE death is announced of Pafnutij Tchebitchef, the eminent Russian mathematician. He was a Foreign Member of the Royal Society, and an Associé Étranger of the Paris Academy of Sciences.

DR. F. B. HAWKINS died on December 7, at the great age of ninety-eight. He was elected a Fellow of the Royal Society sixty years ago, and was one of the oldest members of the medical profession.

THE *Lancet* understands that the Premier has consented to receive a deputation to advocate the formation of a University for London on the lines recommended by the recent Royal Commission. The meeting will probably take place about the middle of January.

THE Paris correspondent of the *Chemist and Druggist* reports that the Municipal Council have presented fifteen hundred francs to the École Normale Supérieure, to erect a bust of M. Pasteur in that college. The Council have also voted in favour of changing the name of the rue d'Ulm to that of "rue Pasteur."

AT the invitation of the associated scientific clubs of Berlin, a numerous assembly met on Friday last in order to commemorate the great services rendered to science by the late Prof. von Helmholtz. The German Emperor and Empress, and many Ministers and members of Parliament, attended the ceremony.

OUR Cambridge correspondent informs us that the Coutts Trotter Studentships in Physics at Trinity College have been awarded for two years to Mr. I. L. Tuckett, and for one year to Mr. S. W. J. Smith, both being scholars of the College.

THE Council of the Marine Biological Association has appointed Mr. E. J. Allen to be director of the Plymouth laboratory, in succession to Mr. E. J. Bles, who lately resigned that position. Mr. Allen is a pupil of Prof F. E. Schultze, of Berlin, and has been engaged in researches upon the cœlomic and nervous systems of Crustacea, some interesting results of which were recently noticed in our columns.

ARRANGEMENTS have been made to begin the new series of *Science* on the first day of the new year, under wholly different direction and auspices. The New York *Nation* says that the paper will hereafter be under the control of a representative editorial committee, and will undertake to report on the progress of science for men of science. The managing committee is constituted as follows:—Mathematics, Prof. Simon Newcomb; Mechanics, Prof. R. S. Woodward; Astronomy, Prof. E. C. Pickering; Chemistry, Prof. Remsen; Physiography, Prof. W. M. Davis; Palæontology, Prof. O. C. Marsh; Morphology, Prof. W. K. Brooks; Zoology, Dr. C. Hart Merriam; Botany, Prof. N. L. Britton; Hygiene, Dr. J. S. Billings; Physiology, Dr. H. P. Bowditch; Ethnology, Dr. J. W. Powell; Anthropology, Dr. D. G. Brinton; Psychology, Prof. Cattell.

THE Organising Committee of the International Geographical Congress have issued an invitation circular to members of geographical societies, and all who take an interest in any of the various aspects of geography, to attend the meetings of the Sixth International Geographical Congress, which will be held in London from July 26 to August 23, 1895. The subjects to be dealt with at the Congress will be grouped under the following heads:—(1) Mathematical Geography; (2) Physical Geography, including Oceanography and Geographical Distribution; (3) Cartography; (4) Exploration; (5) Descriptive Geography; (6) Historical Geography; (7) Applied Geography, including Anthropo-Geography; (8) Education. Intending contributors of papers should send in their communications (written in English, French, German, or Italian) before the end of next April. An exhibition of instruments, maps, globes, photographs, and other objects representative of the present state and past history of geographical science, will be held in connection with the Congress.

DR. E. DE TELLENBERG writes to us, from the Natural History Museum at Berne, with reference to a communication made by Sir John Lubbock to the Geological Society, on November 7 (NATURE, vol. li. p. 94), on some nummulites from the valley of Lauterbrunnen at Murren. Sir John Lubbock remarked that "the find will necessitate a substantial correction of the geological map"; but Dr. de Tellenberg says that the nummulitic layer described was known long ago, and is shown on several geological maps; while the conclusion, that the rock is "not Malm, but Eocene," appears to have been arrived at fifty years ago.

IN a presidential address to the members of the Tyneside Naturalists' Field Club, just received, Prof. G. S. Brady gives an interesting sketch of the present state of fisheries and fish-culture in Great Britain. He describes a visit to Mr. Armistead's successful salmon and trout hatchery near New Abbey, and recommends the foundation of a hatchery on the Northumberland coast to aid in keeping up and improving the supply of sea-fish, and of a biological laboratory attached to it for the scientific study of the marine fauna of the neighbourhood. We hope that everyone interested in the maintenance of our sea-fisheries, and in the study of marine biology in the north-east of England, will cordially assist in the realisation of this timely proposal. A work of this kind, as Prof. Brady suggests, comes fairly within the powers of the County Councils, which have already shown a commendable care for the interests of agriculture, and a desire generally to help forward technical and scientific education.

THE current number of the *Bollettino mensuale* of the Italian Meteorological Society contains a summary, by Profs. A. Bartoli and E. Stracciati, of their determinations of the absorption of solar radiation by fog and by cirrus clouds. The investigations were very carefully conducted, and the results are therefore of considerable interest. It was found that a veil of cirrus was able to intercept as much as 30 per cent. of the sun's rays; while a slight fog, equally diffused in all directions, intercepted from 58 to 92 per cent. of the solar rays, which would have been transmitted with a perfectly clear sky. Full particulars of the numerous experiments made by the authors since the year 1885 will be found in the *Proceedings* of the Royal Institute of Lombardy of July 19 last.

THE Pilot Chart of the North Atlantic Ocean shows that the weather over that ocean during November was very severe. From the 9th to the 23rd of the month there were only two days of good weather between Newfoundland and this country. An appendix to the chart gives the synoptic weather conditions of the North Atlantic north of the 35th parallel for six consecutive days (September 28 to October 3) for the hour of Greenwich noon, showing the positions and behaviour of the various storms which were prevalent at that time. The excellent system adopted by the United States authorities for the collection and discussion of observations made at sea has enabled them to produce this synoptic chart so soon after date. We notice, however, that in the description of the storm signals used in various countries the "cylinder" or "drum" is referred to as now being employed by this country, but as a matter of fact it has not been used for many years.

IN *La Nature* of the 1st instant, M. de Nansouty gives an account of some interesting experiments by M. Kœchlin on the Eiffel Tower, with the view of measuring the force of the wind by the use of metal blocks whose resistance had been previously tested in the laboratory by means of compressed air. During the storm of November 12 last, the velocity anemometers registered 100 miles in the hour, and according to the formula used for the conversion of velocity into pressure, the blocks indicating a pressure of 200 kilograms ought to have been overturned, but only those indicating a pressure of 100 kilograms were displaced. From this, M. Kœchlin concludes that the formula gives results about 40 per cent. too high. It appears to us that the experiments afford a remarkable confirmation of Mr. W. H. Dines's recent investigations of anemometrical constants, in which he found that the usual theory of the cups moving with one-third of the wind's velocity gave values which were about 30 per cent. too high. Experiments very similar to those of M. Kœchlin were made by Mr. G. Dines some years ago, under less favourable conditions, but with nearly similar results.

A PICTURE-PUZZLE of a remarkable kind appears in the *Zoologist* for December. It is a reproduction of two photographs of a Little Bittern, showing the strange attitudes assumed by the bird to favour its concealment. One of the figures shows the bird standing in a reed-bed, erect, with neck stretched out and beak pointing upwards; and in this position, it is difficult to distinguish the bird at all from the reeds. The eye is deceived in a similar manner when the bird is crouching against a tree-stump at the river-side. Mr. J. E. Harting thinks that the curious attitudes adopted by the bird, on finding itself observed, are assumed in the exercise of the instinct of self-preservation. He mentions a similar habit, observed and described by Mr. W. H. Hudson, in the case of a South American Little Heron, which frequents the borders of the La Plata, and is occasionally found in the reed-beds scattered over the pampas. Without the aid of dogs, it was found impossible to secure any specimens of this bird, even after marking the spot where one had alighted.

THE architecture and sculpture of Gastropod shells has often arrested the attention of naturalists, for, in spite of the infinite variety of form assumed by the shell, it is in most cases extremely difficult to perceive any special utility in the nature of the modifications. A paper by Mr. W. H. Dall, however, in a recent number of the *American Naturalist* (No. 335), certainly tends to clear up two sets of these phenomena, viz. the ridges or plications of the columella, and the liræ or teeth of the outer lip. The author shows that among the fusiform rachiglossa the retractor or columellar muscle is longer, and attached deeper within the shell in the plicated (*e.g. Mitra*) than in the non-plicated forms (*e.g. Fusus*). The result of this is that in the former the mantle during contraction is withdrawn into a part of the shell too narrow to admit it in its normal shape. The mantle must wrinkle longitudinally; and the longitudinal shelly ridges on the pillar and towards the aperture of the shell are the mechanical consequences of this plication of the secreting surface. Similarly in forms possessing a very extensive mantle (*Volutidæ*, *Cypræidæ*) it may be noticed that the outer lip of the shell is toothed chiefly in those types in which the aperture is small, and that the denticulation is less marked as the aperture becomes larger. This is attributed by Mr. Dall to the fact that as the aperture becomes reduced the mantle must become increasingly wrinkled at its exit from the shell, thus causing the deposition of teeth and liræ on the outer lip (*c.f. Cypræa*). If these features fall under Prof. Lankester's category of "responsive characters," the question arises whether the whole molluscan shell, so far as its shape and sculpture is concerned, is not simply a combination of such characters.

THE first number of a series of hand-lists of the collections of living plants cultivated in the Royal Gardens, Kew, has just been received. This part, which contains a list of *Polypetalæ*, shows that the complete catalogue will be of the highest service in helping to establish a uniform system of nomenclature. An immense number of "trade" or "garden" names have been reduced to their proper synonyms, and as the woody plants (shrubs and trees), grown in the open air, are particularly liable to confusion in gardens, and in nurserymen's catalogues, the present list is most acceptable. It can easily be understood that the list "represents the work of many years, and has only been accomplished with considerable labour." From the preface we learn that, of the twenty thousand species and distinct varieties of plants cultivated at Kew, three thousand are hardy shrubs or trees. The first catalogue of plants cultivated at Kew, published in 1768, contained 3389 species, of which 488 were hardy trees and shrubs. The two Aiton's published similar lists, but that issued by the younger Aiton early in this century, and containing about eleven thousand species, was the latest comprehensive list of plants in cultivation at Kew, though lists of special collections have been published from time to time. The great importance of the series of hand-lists, which Mr. Thiselton-Dyer has instituted, will therefore be at once understood.

THE twenty-sixth volume of the *Memoirs* of the Russian Geographical Society (General Geography) contains an important work by Prof. Mushketoff and A. Orloff, being a catalogue of all the earthquakes which are known to have taken place in the Russian empire and the adjoining territories of China, Turkestan, Persia, and Asia Minor from the year 596 B.C. till the year 1887. The list comprises no less than 2400 separate earthquakes, of which 710 took place in China, 569 in East Siberia, 36 in West Siberia, 202 in Central Asia, 590 in Caucasia, 121 in North Persia and Asia Minor, and 188 in European Russia and Finland. These figures alone, if compared with those for China in the catalogues of R. Mallet, A. Perrey, and Fuchs, give an idea of the richness of the Russian catalogue. As to Russia, Siberia, and Turkestan, the catalogue is replete with entirely new data. Most of the earthquakes of the last two centuries, for which we possess full accounts, given by careful observers, are described at some length, and some of the descriptions, especially for the earth tremors of Shemakha, Lake Baikal, and Turkestan, are of great value. A map showing the distribution of the earthquakes over the territory, and diagrams showing their frequency during the different months, accompany this most valuable work.

A PAPER on the various more or less phantastic forms assumed by combinations of alkalies with oleic acid when brought into contact with water, is contributed to the current number of *Wiedemann's Annalen*, by Dr. G. Quincke. Oleic acid with little alkali, or containing an acid oleate of an alkali in solution, form in much water hollow spheres, globules, and foam, with walls of liquid oleic acid. The hollow spaces are filled with aqueous soap solution. When more water is added, the walls are covered with a solid skin of the acid oleate, which may then become quite liquid again by decomposition into liquid oleic acid and aqueous soap solution. The periodic flow of soap solution at the surface separating liquid oleic acid and water produces vortex motions, which may be made evident with methylene blue or other colouring matter. More hollow spheres and bubbles of oleic acid are formed, which are arranged by the capillary forces on the larger bubbles in definite positions, such as straight lines, circles, and ellipses. Dr. Quincke points out the remarkable analogy between this arrangement and the configuration of various small portions of the stellar universe, such as portions of Orion, Virgo, and Coma Berenice's, and recalls Plateau's experiments with weightless oil spheres illustrative of the generation of the solar system. He also emphasises the fact that the protoplasm of the organic world shows a structure and motions similar to those of oil foam with liquid or solid surfaces.

UNDER the title, "Science Teaching; an Ideal, and some Realities," Mr. H. G. Wells delivered a lecture at the College of Preceptors last week. Much attention is now being given to the methods of science teaching in our elementary schools and colleges, and Mr. Wells' views on the subject are sound enough to be taken into consideration. In the course of his lecture, he pointed out that a rational course of science should grow naturally out of kindergarten. This should lead to object-lessons proper, and demonstrations in physics and chemistry may be made to grow insensibly, without any formal beginning, out of such lessons. The best, about the only permanently valuable, preparation for a scientific calling that can be given to a boy in a secondary school, is the broad basis of physics and chemistry led up to in this way.

THE 1895 *Annuaire* of the Montsouris Observatory—the Observatory of the Paris Municipal Council—has been published. Though the observations made at the Observatory have special reference to the climatology and hygiene of Paris, researches into the domains of pure science are carried on. M. Léon Descroix has charge of the physical and meteorological service, and M. Albert-Lévy of the chemical part of the work. This department includes the study of the variations in the chemical composition of the air in various parts of Paris, and of rain and river waters. The third branch of the work, dealing with micro-organisms, is under the direction of Dr. Miquel, who contributes to the *Annuaire* his sixteenth memoir on the organic matter found in air and water.

THE papers read at meetings of the Natural History Society of Northumberland, Durham, and Newcastle-upon-Tyne, and the Tyneside Naturalists' Field Club, during the past two years, have just been published in the Society's *Transactions*, vol. xi. part ii. Among them is an address by the President, Prof. G. S. Brady, F.R.S., on the life-history and character of some internal parasites, and a lecture on parasitism in plants and animals. The latter forms one of a series of reports of five lectures given in the Museum of the Society; the others being "On the Egg," by Dr. D. Embleton; "Frogs and Tadpoles," by Prof. M. C. Potter; "The Structure of Timber," by Dr. W. Somerville; and "Germs," by Mr. H. De Haviland. The Society appears to be in a far more flourishing condition than most provincial societies.

SEVERAL new editions of scientific books have been received during the past week. Prof. Richard Hertwig's "Lehrbuch der Zoologie" (Gustav Fischer, Jena) is one of these. The original edition was reviewed in NATURE in June 1893 (vol. xlviii. p. 173), and we have nothing to add to the remarks then made, except that the work has been improved by revision. We are glad to see that Mr. Cumming's "Introduction to the Theory of Electricity" (Macmillan) has reached a fourth edition. The chief additions to the new issue are articles upon the magnetic circuit and on the dynamo. "Symbolic Logic," by Dr. John Venn, F.R.S. (Macmillan), has survived the prejudices of anti-mathematical logicians, for a second edition, revised and rewritten, has just appeared. Finally, Messrs. Whittaker and Co., have issued a second edition of "The Electro-Platers' Handbook," by Mr. G. E. Bonney. This useful manual has been enlarged by an additional chapter on electrotyping, and by a number of short sections on new methods of interest to amateurs and young students of electro-metallurgy.

A BULLETIN (really a volume of 259 pages), by Mr. J. E. Spurr, has come to us from the Geological and Natural History Survey of Minnesota. The subject is "The Iron-Bearing Rocks of the Mesabi Range in Minnesota," and the author treats it from many points of view. A number of reproductions of the appearances presented by thin sections of the rocks when microscopically examined, accompany the memoir. The matter is not merely descriptive of the general structure and characteristics of the Mesabi iron-bearing rocks; if it were, it would only be of local interest. Space is given to the statement of theories to account for the origin of rocks of the kind described—a subject which is still one of doubt, discussion, and speculation. In this connection the origin of glauconite is dealt with. An examination of a thin section, with a view to finding whether the forms in which the glauconitic grains sometimes occur have any resemblance to organic forms, led to a negative result. Mr. Spurr thinks it possible, however, that further study of more favourable sections may result in finding traces of the organisms which possibly once existed in the rocks investigated. His work throws new light upon several perplexing problems in economic geology.

ANHYDROUS hydrogen peroxide has at last been isolated by Dr. Wolffenstein in the laboratory of the Technischen Hochschule at Berlin, and the somewhat surprising fact demonstrated that this substance, which has hitherto been regarded as possessing but little stability, is capable of actual distillation with scarcely any loss under reduced pressure. In attempting to concentrate solutions of hydrogen peroxide *in vacuo* by the method of Talbot and Moody, and also in the open air upon the water bath, a solution as strong as 66 per cent. H_2O_2 was obtained, but with a loss of over 70 per cent. of the original amount of peroxide employed. Moreover, it was found that when the common commercial 3 per cent. solution is concentrated, the percentage of H_2O_2 may be brought up to 45 without the loss of any considerable quantity of the peroxide by volatilisation, but that as the concentration continues to rise above this limit the volatilisation of the peroxide increases at a very rapid rate. For the great loss was proved not to be due to decomposition, but to actual vapourisation of the substance. Evidently hydrogen peroxide is remarkably stable at the temperature of a water bath. An attempt was therefore made to actually distil it under reduced pressure. A quantity of commercial peroxide which had been further concentrated until it contained about 50 per cent. H_2O_2 was first purified from all traces of suspended impurities, and at the same time still further concentrated, by extraction with ether; after evaporation of the ether the solution was found to contain 73 per cent. H_2O_2.

This solution was then submitted to distillation at the temperature of the water bath and under the reduced pressure of 68 m.m. of mercury. The distillate was received in two fractions, boiling at 71°–81° and 81°–85° respectively. The first fraction contained 44 per cent. H_2O_2, while the latter was found to contain no less than 90·5 per cent. Upon again fractionally distilling the latter product, a large proportion distilled at 84°–85°, and this fraction proved to be practically pure H_2O_2, containing over 99 per cent. of the peroxide. The liquid thus isolated is a colourless syrup which exhibits but little inclination to wet the surface of the containing vessel. When exposed to the air it evaporates. It produces a prickly sensation when placed upon the skin, and causes the appearance of white spots which take several hours to disappear again. As regards the much-discussed and disputed question of the reaction of hydrogen peroxide towards litmus, Dr. Wolffenstein finds that even when the pure liquid is made strongly alkaline with soda and again distilled, the distillate exhibits strong acid characters, so that the acid nature of hydrogen peroxide must be regarded as fully established. It is finally shown that the use of ether in assisting the concentration is by no means essential. Ordinary commercial 3 per cent. peroxide can be immediately subjected to fractional distillation under reduced pressure, and a fraction eventually isolated, consisting of the pure substance boiling at 84°–85° under a pressure of 68 m.m.

THE additions to the Zoological Society's Gardens during the past week include a Common Fox (*Canis vulpes*), British, presented by Mr. Harold von Löhr; a Spotted Ichneumon (*Herpestes nepalensis*) from India, presented by the Misses Violet and Sylvia Brockelbank; two Curlews (*Numenius arquata*), British, purchased.

OUR ASTRONOMICAL COLUMN.

SECULAR VARIATIONS OF THE INTERIOR PLANETS.—As far back as 1859, Leverrier discovered that the movement of the perihelion point of the orbit of Mercury was greater than could be accounted for by the action of all the known planets, and he attributed this to the effect of a group of unknown bodies circulating between the orbit of Mercury and the sun. Prof. Newcomb has recently gone over the ground again, and the results of his work are given in *Comptes-rendus* of December 10. A brief statement of the tentative conclusions arrived at was given in these columns on November 29 (p. 114). From a discussion of a vast number of observations he has redetermined the secular variations for the orbits of Mercury, Venus, the Earth, and Mars, and he has computed the masses of Mercury, Venus, and Jupiter from the periodical perturbations which they produce; the adopted value of the earth's mass is deduced from the parallax 8″·80, and for Mars the adopted mass is that derived from observations of the satellites. It is then shown that with these masses the calculated values of the secular variations differ from the observed ones, the divergences being especially great in the movements of the perihelia of the orbits of Mercury and Mars, and of the node of Venus. Two explanations of the differences are open to us: (1) It may be supposed, as suggested by Prof. Asaph Hall, that the law of gravitational attraction is not strictly true, and that the attractive force of the sun varies inversely as the distance raised to the power of approximately 2·0000001574; (2) they may be attributed to the influence of unknown masses of matter.

At first sight, the second hypothesis seems preferable, as it involves no departure from an accepted law, and because it is the only one which will explain all the secular variations, while on the first hypothesis the perihelia would alone be affected. If there are unknown bodies between Mercury and the sun, Prof. Newcomb shows that in order to produce the observed effects, their mass must be great enough to produce a sensible ellipticity in the sun's figure; and as this has not been detected, he prefers to place these unknown bodies between the orbits of Mercury and Venus. He has computed the elements of an orbit which would reduce all the discrepancies between observed and calculated values of the secular variations to less than the probable errors, the mean distance being 0·48, and the mass 1/37,000,000th that of the sun. At the same time, Prof. Newcomb regards this result more as a curiosity than as a reality, as it seems improbable that such a group of bodies should have escaped discovery.

Returning to the other hypothesis, he finds that if we accept Hall's modification of the law of gravitation, which accounts for the movements of the perihelia, the variations of the other elements can all be explained by slightly changing the value of the earth's mass. The new value corresponds to a solar parallax of 8″·77. Although by no means regarding the latter hypothesis as established, Prof. Newcomb is inclined to adopt it provisionally.

IRREGULARITIES IN VARIABLE STARS.—In a summary of the observations of variable stars of long period, made by W. Maxwell Reed at Harvard College Observatory and the Abbot Academy (*Astron. Journ.* No. 330), the importance of studying the irregularities in the light curves is strongly insisted upon. The observations indicate numerous "stand-stills," or notches in the light-curves, and these are believed to be secondary phases produced by additions of light at those points. "A record of over ten years for T Cephei gives ten more or less well-defined stand-stills. The mean period is about twenty days less than that of the variable (about 383 days)." From studying these and other variables, Mr. Reed is inclined to believe that "the light-curve, in some cases at least, is the sum of two or more curves—each component curve having a different range, period, and character from the others. By such a hypothesis one can account for the changes in period and range of a variable, and the presence of "stand-stills" and secondary phases. Unfortunately, there is not enough evidence yet to give the elements of the two or more component curves for T Cephei." It will be remembered that Mr. Lockyer has also seen the necessity for supposing more than one source of variation in many cases, and some of his examples of the peculiar curves produced by integrating two perfectly regular ones were given in our columns four years ago (NATURE, vol. xlii. p. 550). With Mr. Reed we regret that less attention has been given by observers to the character of the light-curves of these variables, than to the determination of the maxima and minima.

THE RADCLIFFE CATALOGUE.—The new star catalogue recently issued by Mr. Stone contains the positions of 6424 stars for the epoch 1890, deduced from observations made with the transit circle at the Radcliffe Observatory between January 1, 1881, and December 31, 1893. Up to 1887 a considerable number of observations were made for the determination of systematic errors of the instrument and for errors of the refraction tables. Since then the observations have been more exclusively directed to obtaining the positions of stars for well-distributed zero-points between the equator and N.P.D. 115°, in continuation and completion of the work carried out under Mr. Stone's direction at the Cape of Good Hope between the years 1870 and 1879. The catalogue gives the positions of all stars down to seventh magnitude between the equator and N.P.D. 115°, except those in clusters; of fainter stars to fill existing lacunæ; and of many stars of greater N.P.D. than 115° for comparison with the Cape catalogue of 1880. Many stars north of the equator are also included. The Cape catalogue and the present one together give a series of well-distributed zero-points for the whole southern hemisphere. With reference to future meridian work, Mr. Stone remarks: "From the facilities which photography affords for the rapid filling in of the positions of the fainter stars on a photographic plate, when those of a sufficient number of zero-points on the plate have been otherwise fixed, it would appear that the efforts of meridian observers will, for the future, be most advantageously directed to this class of stellar work." The catalogue includes estimates of proper motions as well as the usual constants, and there are also copious notes relating to the double and variable stars. The early appearance of a catalogue entailing such a vast amount of computation does great credit to the very limited staff of the observatory.

"L'ASTRONOMIE."—The decease of this monthly journal of popular astronomy is announced in the December number. For thirteen years M. Flammarion has conducted *L'Astronomie*, and has used it to popularise, and extend the study of, astronomical science, and now it dies from "difficultés d'administration." The Société Astronomique de France proposes to attempt to fill the gap by issuing their *Bulletin* monthly instead of quarterly, as heretofore.

ON THE USE OF THE GLOBE IN THE STUDY OF CRYSTALLOGRAPHY.[1]

IN modern treatises on crystallography, the crystal is imagined projected radially on the surface of a sphere, and the spherical triangles so obtained are dealt with by spherical trigonometry. Problems in astronomy and mathematical geography are also commonly dealt with by the methods of spherical trigonometry. But they can also be dealt with completely by the method of graphical construction on the surface of a sphere where the angles and arcs are directly measured with a divided circle; and the use of spherical trigonometry is dispensed with. Many years ago it occurred to the author that what eliminated the use of spherical trigonometry in the one case might eliminate it in the others: hence the idea of the use of the globe in the study of crystallography. Various arrangements of globe and circles were described and exhibited. The usual method of mounting globes on a polar axis, round which it can revolve inside a metal meridian, supported in its turn at right angles to a horizontal circle or equator, was found to be inconvenient. It is necessary to be able to reach every part of the globe, and to have it steady for drawing, and the fixed circle and axes stand greatly in the way of this. The instrument found most generally useful was a black globe, along with a system of brass circles, divided into degrees, which can be applied directly and exactly to any part of its surface. The system of brass circles is called the *métrosphère*, invented by Captain Aved de Magnac, of the French Navy, and published by E. Bertaux, of Paris. With this instrument every problem in the geometry of crystals can be solved with ease and accuracy by graphic construction alone.

The various manipulations occurring in the use of the globes were described and illustrated. In the practical determination of a crystal, the inclinations of its faces are observed with the goniometer. From these observations, treated usually by the methods of spherical trigonometry, the elements of the crystal, namely, the inclination of its axes and the proportion of its parameters, are deduced. The process is then reversed, and the elements found are assumed, and from them the inclinations of the faces are calculated. The usefulness of the globe was illustrated by demonstrating how these two processes can be carried out by simple graphical construction. On the globe, the face of a crystal is represented by its pole, or the point where the radius of the sphere, which is perpendicular to the face, pierces the surface of the sphere. The angle between two faces, measured by the goniometer, is the angle contained between their normals. It is therefore ready to be transferred directly to the globe on which it is entered as an arc. In doing so, any point on the globe is taken as the pole of the face from which a start is made. From this a great circle is drawn in any direction. When the first angle has been measured on the goniometer, it is laid off on the globe as an arc, of an equal number of degrees, along this great circle, and from the initial fixed point. The poles of the first pair of faces are situated at the extremities of this arc, which becomes the *base line* of the survey of the crystal. By triangulation from it, the angles being supplied by the goniometer, the positions of the poles of all the faces are placed as points on the globe.

The intersection of a face with the surface of the globe is a circle, which may be described on it with a pair of compasses, taking the pole of the face as centre. The circles in which any two faces, which are not parallel, meet the sphere, cut each other in two points. If these points be joined by the arc of a great circle, we obtain the projection of the edge which the two faces make on meeting. It is perpendicular to the great circle passing through the poles of the two faces. If it be carried parallel to itself to the centre of the sphere, it coincides with a diameter, and its poles are indicated by points on the globe. When the operation has been repeated with all the edges, we have a second group of points on the globe, which catalogues the edges occurring on the crystals.

If the circles of intersection, with the surface of the sphere, of any three faces, not in the same zone, be considered, the arcs connecting each pair of intersections meet in a point which is the projection of the *corner* formed by the three faces which meet there. A third group of points, representing corners, is thus obtained on the globe, and the characteristics of the crystal are exhausted.

If the corners be carried parallel to themselves to the centre, they find themselves already represented by the intersections of the diameters representing their edges. If the similar poles of any such group of diameters be connected by arcs of great circles, a spherical triangle or polygon is marked out, and its area compared with that of a hemisphere is a measure of the corner, just as the arc is the measure of the angle which it subtends. The secondary figures thus described on the surface of the sphere are always different from the primary ones. Thus the corners of the cube, when collected at and radiating from the centre of the sphere, delineate the regular octahedron, which in its turn, when similarly treated, delineates the cube. From this point of view they are reciprocal inversion forms.

Having got a complete projection of it on the globe, the crystal can be studied. It can be referred with equal ease to any system of coordinates and to any number of different systems; it is only necessary to shift the *métrosphère* over the surface of the globe. In fact, there is now no question touching the geometry of the crystal which cannot be directly answered after making one or more simple measurements; and the distinction between easy questions and difficult ones has almost disappeared.

The projection of the crystal has been constructed from supposed observed angles on the goniometer; but it is equally easy to construct it from its crystallographic specification—that is, the inclination of the axes and the proportion of the parameters.

The projections, of the normals to the faces, or the coordinate planes, are found by constructions on these planes. These positions are marked on the sphere by the points on the coordinate circles where they meet its surface. A great circle drawn through any one point, at right angles to the coordinate circle, contains the pole of the face. It is also contained in another great circle, found in the same way. It is fixed in their point of intersection.

In this way every possible face, permitted by the specification, can be easily and readily placed on the sphere by its representative pole; and the angles between every pair can be at once taken off with a pair of compasses or a tape. In a few minutes a complete catalogue can be made of the angles which each face makes with every other one. The advantage of this is particularly apparent in the oblique systems, which on the globe are dealt with as readily and as easily as those of the regular system.

In conclusion, the author alluded to other uses of the globe, where it does easily, and without fatigue, work which can be done in no other way without great labour; and he pointed out an important indirect advantage, gained by its use, in the education of the sense of direction, which is generally only sparingly developed in the mind.

[1] Abstract of a Paper read before the Chemical Society, December 6, 1894, y J. Y. Buchanan, F.R.S.

THE USE OF SAFETY EXPLOSIVES IN MINES.

A LARGE committee was appointed by the North of England Institute of Mechanical Engineers in 1888, to investigate and report upon the subject of flameless explosives in relation to their degree of safety in mines. Experiments with various explosives and appliances connected with shot-firing were commenced in 1892 at Hebburn-upon-Tyne, and a number of papers referring to them have been contributed to the Institute's *Transactions*. The first part of the Report of the Committee has just been published, and it clears away many of the doubts and uncertainties connected with the employment of safety explosives in underground workings. Into the details of the experiments we have not space to enter, but the following conclusions deduced from them show the kind of results obtained:—

(1) All the high explosives (ammonite, ardeer powder, bellite, carbonite, roburite, and securite) are less liable than blasting-powder to ignite inflammable mixtures of air and fire-damp. These explosives, however, cannot be relied upon as ensuring absolute safety when used at places where inflammable mixtures of air and fire-damp may be present.

(2) The variable results following upon the detonation of high explosives appear to be due in some measure to defective admixture of, or variation in the proportions of, the ingredients used in the manufacture of the explosive.

In view of the changes from time to time made in the proportions and constituents of high explosives, it seems desirable that this information should be afforded by the manufacturers to the users of the explosive.

(3) In the storage of high explosives, it is desirable that every care should be taken to insure their being maintained in a proper condition. It is also certain that these explosives alter in character with age.

(4) It is essential that similar examinations of the working-places and precautions which are in force in mines where blasting-powder is used, should be rigidly observed when a high explosive is employed.

(5) In selecting a high explosive for use in a mine, it should not be forgotten that the risk of explosion is only lessened and not abolished by its use.

(6) All of the high explosives on detonation produce evident flame.

(7) The emission of flame from a blown out shot of a detonated high explosive is not prevented by the quantity or length of stemming used.

(8) In the case of a charge of a high explosive which has missed fire, if a short length of stemming (proved up to 8 inches) has been employed, the charge can be detonated by another cartridge of the explosive and additional stemming being placed in the hole in front of the original stemming.

The experiments were carried out under the direction of Mr. J. L. Hedley, H.M. Inspector of Mines, and Mr. A. C. Kayll, the Engineer to the Committee.

The sincere thanks of mining engineers are due to the Institute for bearing the great expense involved by the experiments, and to the many mining companies, associations, and private firms that have rendered valuable assistance in the matter.

THE UPSALA MEETING OF THE INTERNATIONAL METEOROLOGICAL COMMITTEE.[1]

AT the meetings of the International Meteorological Committee, held at the University of Upsala, in August, the secretary submitted a brief report, with the questions proposed for discussion. A statement of these, with the decisions, follows:—

International Bureau.—A report was presented by Prof. Hildebrandsson, in which the functions and cost of such a bureau were considered. The committee decided against its establishment.

Agricultural Meteorology.—Upon the proposition of Mr. Scott, it was decided that the methods employed to distribute weather predictions to farmers, and the results of climatological discussions relating to the crops in the various countries, be published.

Establishment of Stations for Cloud Observations.—Prof. Hildebrandsson presented a pamphlet containing a detailed account of the principal methods employed in these investigations. The committee adopted these resolutions:—

Since experience shows that the altitude of clouds can be easily determined with sufficient accuracy, the generalisation of these investigations in all countries is recommended, preferably by the use of the photographic process. Observations of direction and relative velocity should be made at as many stations as possible, and measures of height at a limited number of suitably distributed stations.

The value of these investigations would be greatly increased if made at the same epoch, therefore it is proposed that they be commenced May 1, 1896, and continued for one year.

The stations already promised are situated in Batavia, France, Norway, Portugal, Prussia, Roumania, Russia, Sweden. United States: Blue Hill, and Weather Bureau (six stations).

Cloud Atlas.—The committee appointed at Munich reported slightly modified definitions of some types in the Hildebrandsson-Köppen-Neumayer Atlas, and submitted photographs and pastels for reproduction in the new atlas, as well as instructions for observing clouds. These were adopted by the Permanent Committee after discussion and modification. (See subjoined report.) A special committee, composed of M. Teisserenc de Bort and Prof. Riggenbach, with Prof. Hildebrandsson as chairman, was appointed to publish the atlas, and the choice of the colour of each place, to represent as nearly as possible the natural conditions, was left to its discretion.

More Rapid Transmission of Telegrams.—Dr. Snellen presented a joint report with Dr. Neumayer on this question, in which the necessity of giving the meteorological dispatches precedence over others, by opening a circuit system with the other central bureaus, was urged. The introduction of simultaneous observations in the various countries was deemed necessary. The committee referred the matter to the International Telegraphic Bureau at Berne.

In more or less intimate relation with this question was a proposition by Dr. van Bebber, on the importance of further experiments in tele-meteorography. Dr. Snellen explained the telegraphic transmission of the traces of self-recording instruments by the Olland apparatus, which operates over a short distance at Utrecht.

Scintillation of Stars.—At the request of M. Ch. Dufour, this question, which had been the object of investigations by M. Montigny, of Brussels, was brought before the committee. Further study by him, together with that of M. Ventosa, on the atmospheric movements observed around stars, was encouraged.

Maritime Meteorology.—A proposition of the Russian Admiral Makaroff, on the necessity of an international convention to arrange for the discussion of the data contained in ships' logs, was not approved.

Psychrometric Observations below Freezing.—This question was introduced by Profs. Hildebrandsson and Mohn. The employment of Ekholm's method for the reduction of mean values was recommended, but a report of further investigations was requested.

Exploration of Upper Air.—A resolution received from the *Congrès de la Science de l'Atmosphère*, which had recently met in Antwerp, on the importance of the balloon ascents now being made at Berlin for meteorological purposes, was confirmed in a more general sense.

Next Congress.—It was decided to convene a non-official congress at Paris in September 1896.

THE CLASSIFICATION OF CLOUDS.

In the cloud classification of Hildebrandsson and Abercromby, published in the Hildebrandsson-Köppen-Neumayer Atlas, in 1890, the word "diurnal" is added to the definition of Group D, so that it becomes:—

D. Clouds formed by the diurnal ascending currents.

In this way, the cumulus arising from a mass of aqueous vapour ascending through calm air is distinguished from the nimbus caused by the general ascension of the whole mass of moist air.

With this change the classification of the ten principal forms is:—

(*a*) Detached or rounded forms (most frequent in dry weather).
(*b*) Wide-spread or veil-like forms (wet weather).

A. Highest clouds, mean height 9000 metres.
 (*a*) 1. Cirrus.
 (*b*) 2. Cirro-stratus.
B. Clouds of mean altitude, 3000–7000 metres.
 (*a*) { 3. Cirro-cumulus.
  4. Alto cumulus.
 (*b*) 5. Alto-stratus.
C. Low clouds, 1000–2000 metres.*
 (*a*) 6. Strato-cumulus.
 (*b*) 7. Nimbus.
D. Clouds formed by the diurnal ascending currents.
 8. Cumulus. Top, 1800 metres; base, 1400 metres.
 9. Cumulo-nimbus. Top, 3000–5000 metres;* base, 1400 metres.
E. Elevated fog, below 1000 metres.
 10. Stratus.

N.B.—As the heights of the clouds marked * do not agree with the heights of these clouds found at Blue Hill, Mr. Rotch has asked that the altitude of the low clouds be placed below 2000 metres simply, instead of between 1000 and 2000 metres, since the bases of nimbus are frequently below 1000 metres; and also that the superior limit of the tops of the cumulo-nimbus be raised to 8000 metres.

The following are descriptions of the clouds, modified from those in the Hildebrandsson-Köppen-Neumayer Atlas.

[1] Extracted from a report by Mr. A. Lawrence Rotch, in the December number of the *American Meteorological Journal.*

(1) CIRRUS (Ci.).—Isolated feathery clouds of fine fibrous texture, generally of a white colour. Frequently arranged in bands which spread like the meridians on a celestial globe over a part of the sky, and converge in perspective towards one or two opposite points of the horizon. (In the formation of such bands, Ci. S. and Ci. Cu. often take part.)

(2) CIRRO-STRATUS (Ci. S.).—Fine whitish veil, sometimes quite diffuse, giving a whitish appearance to the sky, and called by many cirrus haze, sometimes of more or less distinct structure, exhibiting confused fibres. The veil often produces halos around the sun and moon.

(3) CIRRO-CUMULUS (Ci. Cu.).—Fleecy cloud. Small white balls and wisps without shadows, or with very faint shadows, which are arranged in groups and often in rows.

(4) ALTO-CUMULUS (A. Cu.).—Dense fleecy cloud. Larger whitish or greyish balls with shaded portions, grouped in flocks or rows, frequently so close together that their edges meet. The different balls are generally larger and more compact (passing into S. Cu.) towards the centre of the group, and more delicate and wispy (passing into Ci. Cu.) on its edges. They are very frequently arranged in stripes in one or two directions.

(The term cumulo-cirrus is given up as causing confusion.)

(5) ALTO-STRATUS (A. S.).—Thick veil of a grey or bluish colour, exhibiting in the vicinity of the sun and moon a brighter portion, and which, without causing halos, may produce coronæ. This form shows gradual transitions to cirro-stratus, but, according to the measurements made at Upsala, has only half the altitude.

(The term stratus-cirrus is abandoned as giving rise to confusion.)

(6) STRATO-CUMULUS (S. Cu.).—Large balls or rolls of dark cloud which frequently cover the whole sky, especially in winter, and give it at times a wave-like appearance. The stratum of strato-cumulus is usually not very thick, and blue sky often appears in the breaks through it. Between this form and the alto-cumulus, all possible graduations are found. They are distinguished from nimbus by the ball-like or rolled form, and because they do not tend to bring rain.

(7) NIMBUS (N.).—Rain clouds. Dense masses of dark formless clouds with ragged edges, from which generally continuous rain or snow is falling. Through the breaks in these clouds there is almost always seen a high sheet of cirro-stratus or alto-stratus. If the mass of nimbus is torn up into smaller patches, or if smaller clouds are floating very much below a great nimbus, the former may be called Fracto-nimbus ("Scud" of the sailors).

(8) CUMULUS (Cu.).—Piled clouds. Thick clouds whose summits are domes with protuberances, but whose bases are flat. These clouds appear to form in a diurnal ascensional movement which is almost always apparent. When the cloud is opposite the sun, the surfaces which are usually seen by the observer are more brilliant than the edges of the protuberances. When the illumination comes from the side, this cloud shows a strong actual shadow; on the sunny side of the sky, however, it appears dark with bright edges. The true cumulus shows a sharp border above and below. It is often torn by strong winds, and the detached parts (Fracto-cumulus) present continual changes.

(9) CUMULO-NIMBUS (Cu. N.).—Thunder cloud; shower cloud. Heavy masses of clouds, rising like mountains, towers, or anvils, generally surrounded at the top by a veil or screen of fibrous texture ("false cirrus"), and below by nimbus-like masses of cloud. From their base generally fall local showers of rain or snow, and sometimes hail or sleet. The upper edges are either of compact cumulus-like outline, and form immense summits, surrounded by delicate false cirrus, or the edges themselves are drawn out like cirrus. This last form is most common in "spring squalls." The front of storm clouds of great extent sometimes shows a great arch stretching across a portion of the sky, which is uniformly lighter in colour.

(10) STRATUS (S.).—Lifted fog in a horizontal stratum. When this stratum is torn by the wind or by mountain summits into irregular fragments, they may be called Fracto-stratus.

INSTRUCTIONS FOR OBSERVING CLOUDS.

At each observation there are to be recorded:—

(1) *The Kind of Cloud*, designated by the international letters of the cloud name, which may be more exactly defined by giving the number of the picture of the Atlas most nearly representing the observed form.

(2) *The Direction from which the Clouds come.*—If the observer remains completely at rest during a few seconds, the motion of the clouds may be easily observed relatively to a steeple or mast erected in an open space. If the motion of the cloud is very slow, the head must be supported. Clouds should be observed in this way only near the zenith, for if they are too far away from it the perspective may cause errors. In this case nephoscopes should be used, and the rules followed which apply to the particular instrument employed.

(3) *Radiant Point of the Upper Clouds.*—These clouds often appear in the form of fine parallel bands, which, by an effect of perspective, seem to come from one point of the horizon. The radiant point is that point where these bands, or their direction prolonged, meet the horizon. The position of this point on the horizon should be recorded in the same way as the wind direction, north, north-north-east, &c.

(4) *Undulatory Clouds.*—It often happens that the clouds show regular, parallel, and equidistant streaks, like the waves on the surface of water. This is the case for the greater part of the cirro-cumulus, strato-cumulus (roll-cumulus), &c. It is important to note the direction of these streaks. When there are apparently two distinct systems, as is to be seen in clouds separated into balls by streaks in two directions, the directions of the two systems should be noted. As far as possible, observations should be made on streaks near the zenith to avoid effects of perspective.

(5) *Density and Position of Cirrus Banks.*—The upper clouds frequently take the form of felt or of a more or less dense veil, which, rising above the horizon, resembles a thin white or greyish bank. As this cloud form has an intimate relation to barometric depressions, it is important to note:—

(*a*) The density—

0 meaning very thin and irregular.
1 meaning thin but regular.
2 meaning rather dense.
3 meaning dense.
4 meaning very dense and of dark colour.

(*b*) The direction in which the veil or bank appears densest.

Remarks.—All interesting details should be noted, for example:

(1) On summer days all low clouds generally assume particular forms resembling cumulus more or less. In this case, there should be put under *Remarks*, "Stratus or Nimbus Cumuliformis."

(2) It sometimes happens that a cumulus has a mammillated lower surface. This appearance should be described by the name of "Mammato-cumulus."

(3) It should always be noted whether the clouds appear stationary, or whether they have a very great velocity.

The text of the Atlas is to be in French, English, and German.

ENDOWMENT FOR SCIENTIFIC RESEARCH AND PUBLICATION.[1]

II.

IMMEDIATELY connected with our colleges and universities is another field, in which additional endowments are greatly needed, viz. for fellowships in science for post-graduate studies.

Upon the post-graduate workers the future of science, and the recruits for future teachers and professors, must necessarily depend. In that view the importance of post-graduate endowments in science can scarcely be magnified. The great majority of the young men from whom all the new recruits must be drawn have little or no pecuniary means. After graduating, often through many difficulties, they must face the question of their future calling. They must consider what promise of a reasonable and comfortable support a life devoted to science affords. If this risk should not deter them, still there are many with talents of a high order who would be absolutely unable to proceed further in the advanced scientific studies necessary to qualify them to enter upon remunerative scientific

[1] Address delivered by Mr. Addison Brown, at a meeting of the Scientific Alliance of New York. Reprinted from Smithsonian Report, 1892. (Continued from page 167.)

work, or to obtain situations as professors or assistants, except by the aid of substantial endowments for their support, during the three or four years more of necessary assiduous study.

In the stress of modern life, and in the allurements towards more certain pecuniary results, nothing but such endowments can avert the withdrawal from scientific pursuits of many young men of high promise, whose genius and tastes and ambition strongly incline them to science, and who would be secured to it if this temporary support were afforded.

The endowments of our colleges and universities in aid of post-graduate work in science are much less, I suppose, than is commonly imagined. I find no such support for post-graduate work in science, either at Cornell University, at the University of the City of New York, at Brown University, at Amherst, or even at the Johns Hopkins University. No statement of the endowments of the new Clark University at Worcester has as yet been published. Princeton, though having a hundred under-graduate scholarships, has but one post-graduate fellowship for science; Yale but two—the Silliman and the Sloane Fellowships.

Columbia College has two fellowships expressly restricted to science, viz. the Tyndall Fellowship of 648 dols. annually, and the Barnard Fellowship, before referred to, of about 500 dols. annually. Besides these, however, twenty-four general university fellowships have been established, of 500 dols. each, for post-graduate study, of which eighteen are in present operation. About one-third of these are assigned to science; making now eight for science at Columbia, with probably two more in 1893 or 1894. In architecture, moreover, there are three additional noble post-graduate fellowships at Columbia—the Schermerhorn of 1300 dols. annually, and the two McKim Fellowships of 1000 dols each, to support study in foreign travel. In the Medical Department, also, there are five valuable prizes for proficiency.

The University of Pennsylvania has the Tyndall Fellowship, before referred to; and, in the Department of Hygiene, an admirable laboratory fitted up by Mr. Henry C. Lea, with a fellowship of 10,000 dols. endowed by Mr. Thomas A. Scott, at present applied to original research in bacteriology.

At Harvard, besides the three Bullard Fellowships of 5000 dols. each, established in 1891, to promote original research in the medical school, there are two post-graduate fellowships restricted to science exclusively, namely, the Tyndall Fellowship of about 500 dols. annually, and the income of the recently established Joseph Lovering Fund, the principal of which is now about 8000 dols. There are also eleven other general fellowships, viz. the Parker, the Kirkland, and the Morgan Fellowships, available for promising graduate students in any branch, of which about five have been usually assigned to science. These fellowships give an income of from 450 dols. to 700 dols. a year. Harvard has also forty-six scholarships available for graduate students varying in income from 150 dols. to 300 dols. each, of which about seventeen are assigned to science. During the last year, according to the report of Prof. Pierce, the Dean, there were 193 applications for those post-graduate fellowships and scholarships, seventy-one of which were in science. Only one-third of the applicants could receive the aid. The Dean adds:

"The number of appointments is still *very insufficient* to meet demands of promising students who wish to enter the graduate school, and are unable to do so without assistance." (Report Harvard Coll. 1891, p. 92.) The tables published by him indicate that a considerable number of those not aided withdrew from science; and that many others who were entered for the first year in the graduate school would, if not aided, afterwards leave. It is gratifying to observe the further fact, so encouraging also for the young graduates who wish, if possible, to enter upon a scientific career, that all who had enjoyed these fellowships for the full term of three years, andd id not coninue their studies further abroad, at once received honourable tpositions.

From the above synopsis it appears that in all these colleges (and I know of no other similar fellowships elsewhere) there are only about twenty-six adequately endowed post-graduate fellowships in science. As these should be continued for at least three years, there is provision altogether for only about nine per year—not one-fourth the number required to supply the annual loss in our 150 colleges, to say nothing of the increasing demand through the growth and improvements in the colleges themselves. As it is from such specially trained students that the great professors of the future must be drawn, the need of much greater endowments for new recruits is apparent.

In England the aids afforded by fellowships in their universities are familiar to all. Sir Isaac Newton, who is to modern science what Shakespeare is in literature, was sustained from his student days successively in a scholarship, a fellowship, and as professor at Trinity College at Cambridge. Besides those aids, the Royal Commissioners of the Exhibition of 1851 instituted in 1891 "Exhibition Science scholarships" for advanced students, to which 25,000 dols. yearly is to be applied in sums of 750 dols. each. In the first year sixteen appointments were made, to be held for two, and probably for three, years by students who show capacity, and "who advance science by experimental work."[1]

On this subject a most interesting discussion took place last year in the French Academy of Sciences. On April 27, 1891, the Secretary read the following extracts from the will of the late M. Cahours, a deceased member of the Academy:

"I have frequently had the opportunity of observing, in the course of my scientific career, that many young men distinguished and endowed with real talent for science, found themselves obliged to abandon it, because before beginning they had no efficacious help which provided them with the first necessities of life, and allowed them to devote themselves exclusively to scientific studies.

"With the object of encouraging such young workers, who for want of sufficient resources find themselves powerless to finish works in course of execution, . . . I bequeath to the Academy of Sciences . . . 100,000 francs, . . . the interest to be distributed yearly by way of encouragement to any young men who have made themselves known by some interesting works, and more particularly by chemical researches; . . . as far as possible to young men without fortune, not having salaried offices, and who, from want of a sufficient situation, would find themselves without the possibility of following up their researches. These pecuniary encouragements ought to be given for several years to the same young men, if the Commissioner thinks their productions have sufficient value; . . . to cease when they shall have other sufficiently remunerative positions."

M. Janssen, then addressing the Academy, said:

"This affords an example to all who hereafter may desire to encourage the sciences by their liberality. M. Cahours, who knew the urgent necessities of science, had, like most of us, become convinced of the need of introducing a new form of scientific recompenses.

"Our prizes will always continue to meet a great and noble necessity. Their value, the difficulty of obtaining them, and the *éclat* they take from the illustriousness of the body that grants them, will always make them the highest and most valuable of recompenses. But the value also of the works it is necessary to produce in order to lay claim to them forbids them to beginners. It is a field only accessible to matured talents. But there are many young men endowed with precious aptitudes, inclined to pure science, but turned very often from this envied career by the difficulties of existence, and taking with regret a direction towards more immediate results. And yet many among them possess talents which, if well cultivated, might do honour and good to science. . . . These difficulties are increased every day by the marked advance of the exigencies of life.

"We must find a prompt remedy for this state of things, if we do not wish to see an end of the recruitment of science. This truth is beginning to be generally felt. The Government has already created institutions, scholarships, and encouragements, which partly meet the necessity. Some generous donors are also working in this manner. I will mention specially the noble foundation of Mdlle. Dosne, in accordance with whose instructions a hall is at this moment being built, where young men, having shown distinguished aptitudes for high administration, for the bar, or for history, will receive for three years all the means of carrying on high and peaceful studies. Let us say, then, plainly (and in speaking thus we only feebly echo the words of the most illustrious members of the Academy), that it is by following the way so nobly opened by Cahours that the interests and prospects of science will be most efficaciously served."[2]

Huxley is said to have once stated that "any country would find it to its interest to spend 100,000 dols. in first *finding* a Faraday, and then putting him in a position where he could do

[1] Sir William Thomson, *Proceedings, Royal Society*, 1891, vol. l. p. 225.

[2] NATURE, May 7, 1891 (vol. xliv. p. 17).

the greatest amount of work." It is the post-graduate endowments that must first find and retain to science the Faradays of the future.

A notable instance of the need and value of such aid is found in the recently-appointed head of a great university, who, by such endowments alone, here and abroad, it is said, was enabled to prosecute his studies for ten years successively, reaching thereby the front rank in his chosen department of philosophy.

III.

Another department in great need of pecuniary support is that of the learned and scientific societies. In these England is pre-eminent. Our own societies have endeavoured to follow, as far as they could, their English models. The English societies have rendered to science invaluable service in three main lines:

1. In providing ample means for the publication of scientific papers, showing the progress and the results of their scientific work. In this every society has taken part.

2. In the direct maintenance of original research, in which the Royal Institution has been most conspicuous.

3. In the award of prizes for scientific distinction; but still more important, in the distribution of pecuniary aid, for the prosecution of special scientific researches.

(1) Of these, I regard publication as, perhaps, the most important; not only because it puts the world in possession of what has been done by investigators, but because the very fact that there are means of publication, is one of the greatest incitements to complete and thorough original scientific work.

Of the English societies the Royal Society is the oldest, having been chartered in 1662. It has published 181 volumes of *Transactions* and about 50 volumes of *Proceedings*. For these purposes, in 1881 the expenditure was between 11,000 dols. and 12,000 dols. It has property to the value of about two-thirds of a million of dollars, more than half of which is in trust funds, held for scientific uses. The income on the trust funds in 1891 was about 17,500 dols. (*Proceedings*, 1891, vol. l. p. 235.) In 1828 Dr. Wollaston, in giving it 10,000 dols. in 3 per cent. Consols "to promote scientific researches," charged upon the Society "not to hoard the income parsimoniously, but to expend it liberally for the objects named."

The Royal Institution of Great Britain was founded in 1779, largely through our countryman James Thompson, of Rumford, Vt., afterwards Count Rumford. In 1888 it had property and invested funds for general purposes to the amount of 350.000 dols., and about 40,000 dols. of invested funds for the maintenance of its three professors. In 1887 it expended about 2000 dols. in publications, and it has issued about forty volumes. (*Report*, 1888, p. 13.)

The Linnean Society, now furnished by the Government with permanent accommodation in Burlington House, free of rent, was founded by Sir James E. Smith in 1788, and is devoted to botany and zoology. Its property amounts to about 32,000 dols., but it has no endowed funds for scientific investigation. For some years past its receipts, mainly from contributions, have been about 10,000 dols. a year, of which one-half, about 5000 dols., is spent on its publications, which now number nearly fifty volumes of *Transactions* in quarto, and as many more of its *Journal*. In 1888 7000 dols. were expended in publication. (*Proceedings* [May 4, 1888], 1890, pp. 15, 45.)

Next in order of time is the British Association for the Advancement of Science, founded in 1831. It is sustained chiefly by yearly contributions. Its invested funds amount to about 62,000 dols. Its income and contributions are about 10,000 dols. annually, out of which it appropriates from 6000 dols. to 7000 dols. per annum for the encouragement of scientific investigations, and about 1800 dols. annually for its yearly volume of *Proceedings*. Its publications now number twenty-five volumes. (*Report*, 1891, pp. lxxxvii. to c. 76.)

The Ray Society was founded in 1844. It was named after the Rev. John Ray, who lived from 1628 until 1705. Haller, himself one of the greatest men of science of his time, writing in 1771, in the full light of Linnæus' fame, calls Ray "the greatest botanist within the memory of man." (*Bibliotheca Botanica.*) The society has published about fifty volumes of scientific works of the highest importance. I have not seen any statistics concerning its means or acquisitions; nor have I found any financial report of the scientific societies of Edinburgh or Dublin.

(2) Of these societies, only the Royal Institution directly supports professors for scientific research. It has two laboratories, one chemical and one physical. These were rebuilt in 1872, "in order that original discovery might be more effectively carried on." The society was founded for the declared purpose of "promoting scientific and literary research." It has three professors—one in chemistry, one in physics, and one in physiology. Davy, Faraday, Tyndall, and others who have spent their lives there, have made its annals immortal.

(3) In stimulating research by the appropriation of moneys for specific objects, the Royal Society and the British Association are the chief agencies. Besides some of its own funds, the Royal Society distributes annually £4000, or 20,000 dols., granted by the Government "for the advancement of science." This has been done by applying it to numerous purposes; in 1891, for fifty-seven different scientific objects, in sums ranging from 25 dols. to 3000 dols. each; not confined to natural science alone, but including ethnology and magnetic surveys. Most of the grants were in sums of about 350 dols. or less. (*Proceedings*, 1891, vol. l. p. 242.)

The British Association has disbursed annually for the last forty years from 6000 dols. to 7000 dols. per annum, upon the same system of dividing it up for numerous specific purposes; usually from thirty to forty objects yearly, the grants being in sums ranging from 25 dols. to 1000 dols. The grants are called for and expended for the specific purpose named, and under the direction of some prominent scientific man. Men of science like Sir William Thomson, and others of like renown, have had the administration of many of these grants. These have included for the last six years (save in 1890) the appropriation of 500 dols. per year for a table in the Naples Marine Laboratory. (*Report*, 1890, p. 90.)

We have no single society in this country, save the Smithsonian, that can rival in importance those that I have named in England. And the Smithsonian is not a society, but an institution, established by one man, and he an Englishman. This institution, based upon the bequest of James Smithson, was founded by act of Congress of August 10, 1846. I doubt whether in any country or in any age the bequest of half a million of dollars has ever been followed by such beneficent results, or has ever so profoundly affected the life of science in any country as the Smithsonian Institution has done in America during the last forty-four years of its existence. This has been owing (1) to the wisdom and the profound scientific insight of Prof. Henry, its first secretary and director; and (2) to the corps of able assistants and successors whom his spirit and policy have inspired. Its publications number 26 quarto volumes of "Contributions to Knowledge," 40 volumes of "Miscellaneous Collections," and 44 volumes of "Annual Reports." Its "Contributions to Knowledge" rival, if they do not excel, in rarity and importance, the publications of any other society during the same period. Its expenditure in publications is about 12,500 dols. a year. Under Prof. Henry a good deal was done in research. Under Prof. Langley, the present director, astro-physical research is carried on. Besides the direct scientific work of the Institution, however, its influence has been very great, especially in its relations with the other departments at Washington, and as a medium for the prosecution of other scientific enterprises under authority of Congress. Many of the appropriations of Congress for scientific expeditions for researches in ethnology, palæontology, chemistry, and physics have been due to the presence and co-operation of the Smithsonian Institution. For ethnologic researches alone during the last twelve years, under the administration of the Smithsonian, Congress has appropriated 400,000 dols.; to palæontologic researches within the last three years, 160,000 dols.; to chemical and physical research, 68,000 dols.; and to astro-physical research, 10,000 dols. Besides these, there have been for many years appropriations for maintaining the important investigations of the Coast and Geodetic Survey, and of the Weather Bureau in Meteorology; and for the great scientific work of the Naval Observatory, and of the various scientific divisions of the Agricultural Department and of the Geological Survey. Our Government has been by no means inactive in science.

The principal American scientific associations, omitting those of comparatively recent origin, are the American Philosophical Society of Philadelphia, originally founded in 1744; the American Academy of Arts and Sciences at Boston; the Boston Society of Natural History; the Academy of Natural Sciences; and the Franklin Institute at Philadelphia, the latter founded in 1824 (see *Journal*, vol. i. pp. 71, 129); the New York Academy of Sciences (a continuation of the Lyceum of Natural History); the National Academy of Science at Washington, founded in 1863; and the American Association for the Advancement of Science. Of these, the Philosophical Society has published 29 volumes of its *Transactions;* the American Academy, 26 volumes of *Transactions* and 9 quarto volumes of *Memoirs;* the Boston Society of Natural History, 25 volumes, at a cost of about 600 dols. per year; the Academy of Natural Science of Philadelphia, 48 volumes of *Proceedings* and 12 quarto volumes of its *Journal*, at an average cost of about 1000 dols. per year; the Franklin Institute, 133 volumes of its *Journal;* the New York Academy and its predecessor, about 30 volumes of *Transactions* and *Annals;* the National Academy, 3 quarto volumes of *Memoirs* and some volumes of *Proceedings;* and the American Association for the Advancement of Science, about 40 volumes of *Proceedings*.

The latter society had in 1891 a "Research Fund" of 5254 dols. (*Proceedings*, 1891, p. 441.) None of the other societies, so far as I can find, has any fund specially devoted to research, or makes any specific appropriations therefor. The National Academy and the Academy of Philadelphia have each some funds for their support, and the latter also the Jessup Fund for students in science, on which the income is about 550 dols. yearly. The Philosophical Society from time to time awards the prize established by John Hyacinth de Magellan in 1786—an oval gold plate "for the most useful discovery or invention in navigation or science." One of the earliest awards of this prize was for painting lightning-rods with black lead.

The American Academy of Arts and Sciences awards a gold and silver medal from a bequest of 5000 dols. made to it by Count Rumford, who in 1796 made a similar bequest to the Royal Society. In 1888 this prize was most worthily awarded to Prof Michelson for his researches in light.[1]

The Boston Society of Natural History has a general fund, of which the income is about 6000 dols. It has also a small Walker prize fund and a grand prize fund, from which in 1884 it awarded a grand prize of 1000 dols. to James Hall, of Albany, "for his distinguished services to science." It also administers the expenditure of about 2700 dols. a year for instruction in laboratory work, drawn from the Boston University, and 1500 dols. from the Lowell Fund for the instruction of teachers.[2]

From this comparison of the voluntary associations, it appears that the property, endowed funds, and equipment of the English societies named are nearly tenfold greater than the American, and their publications double; while for direct original research our societies maintain no laboratories and no professors, as is done by the Royal Institution. The English societies distribute yearly from 25,000 dols. to 30,000 dols. for from sixty to seventy-five different scientific purposes, while ours make no such appropriations, simply because they have no funds. To supply this deficiency there is need of large endowments.

The publications of our societies are valuable; the papers have often been of a high character, rivalling those published abroad. But the funds available for publication are insufficient; it is always a question of means. There are a press and surplus of valuable scientific matter, which either is not printed at all, or only gets printed by special subscriptions for the purpose. This ought not to be. After valuable original matter has been produced with great pains and without hope of pecuniary reward, nothing is more discouraging to future research than that even publication can only be had as a charity. This I know, from repeated personal applications, is the condition of things in New York at this moment. It is not creditable that, in a State and country like ours, there should be practically nowhere adequate provision for even the publication of the researches of those who work for nothing but their love of science and its progress. There is very great need of a considerable publication fund, in the hands of some scientific body, through which every valuable contribution to science, not otherwise provided for, might be ensured a speedy publication, after it has been found worthy, as in the practice of the Linnæan Society, first by a critical expert in the particular department, and then by the council of publication.[3]

The stimulus, moreover, to scientific research that would be imparted by the distribution of comparatively small sums, such as are given by the Royal Society and by the British Association, would also be very great; nor is there any reason why the founding of professorships for the express purpose of prosecuting original research in our scientific societies, after the model of the Royal Institution, should not in time be followed by results equally brilliant, and equally beneficial to mankind.

I have endeavoured to point out three main directions in which there is urgent need in this country of pecuniary endowments.

(1) In relief of professors during the transition of the colleges from the schoolmaster system to the university system, whereby all professors in science shall become actively enlisted in the prosecution of original discovery as a part of their duties.

(2) In providing for the future recruits in science, by more endowments for post-graduate study.

(3) By endowments of our scientific associations, both directly to promote original research, and especially also to supply larger means of publication.

It is gratifying to perceive what beginnings have been recently made in response to the needs of science. Only a short time since, in 1885, Mrs. Elizabeth Thompson, of Stamford, Conn., gave 25,000 dols. to a board of trustees of which Dr. Bowditch, of Boston, is president, for the "advancement of scientific research in its broadest sense." The income is annually distributed in sums of from two hundred to five hundred dollars.

Mr. Hodgkins, of Setauket, Long Island, has bequeathed to the Smithsonian Institution 200,000 dols., the income of one-half of which is to be devoted to research into the properties of atmospheric air.

Columbia College has, during the year 1891, received from Mr. Da Costa's estate, before referred to, 100,000 dols. for biology; Harvard, the Joseph Lovering Fund, above stated; 10,000 dols. from Henry Draper for the photography of stellar spectra; the endowments in archæology, above named; and some smaller gifts for various scientific purposes. The University of Chicago and some other institutions have also received important gifts, not to mention those yet to be realised to other colleges from the estate of Mr. Fairweather.

By a bequest of Charles Lenning, the Academy of Sciences of Philadelphia will, in time, receive 20,000 dols.; while half a million of dollars will go to the University of Pennsylvania in aid of instruction in theoretical and practical mechanics, and 200,000 dols. to maintain scholarships. At this University, also, a superb structure for the "Wistar Institute of Anatomy" is now building by General Isaac J. Wistar, at a cost of about 200,000 dols., including endowments designed for original research.[1]

Our reliance in this country must be mainly upon private endowments and the intelligent appreciation of the needs of science. The national Government has done, and is doing, much in certain directions. But aside from the dispositions of legislators, it is restricted by the provisions of the Federal Constitution, and by debated questions of constitutional right. State aid is not thus hampered; but State aid is difficult to obtain, to any adequate degree, on account of the previous habits, prejudices, and political training of the people. No doubt this ought not so to be. The State of New York ought, abstractly considered, to maintain one university of the first class equal in every department to any in the world. But the multiplication of institutions already existing, local jealousies, and aversion to State taxation, make this now probably impracticable.

The remedy is with the people, and through their own voluntary methods. It is the people who have made our Government, its institutions, its methods, and the great aggregate, whatsoever it is, such as we see it to-day. Wealth is rapidly accumulating; much of it in the hands of those who, springing from the people, bear the love of the community in their hearts; and when they and the people at large shall come to see that the cause of scientific advance and the discovery of all new truth are in the deepest sense their cause, responses will, I believe, come to every urgent need; until the work of the people, by its own methods, shall, even in science, be able to confront, without shame, the best work of the monarchies of the Old World.

[1] President Lovering's Address, *Proceedings*, vol. xxiv. p. 380.
[2] *Proceedings*, vol. xxiv. p. 14
[3] President Carruthers, *Proceedings, Lin. Soc.*, May 1890, p. 39.

[1] Since the above was written an additional million of dollars has been given by Mr. John D. Rockefeller to the University of Chicago, making 3,600,000 dols. given by him alone to that institution within less than three years, a munificence hitherto unexampled in private endowments, some portions of which, it is hoped, will be available for the maintenance of original scientific research.

SCIENTIFIC SERIALS.

American Journal of Science, December. — Inversion of temperatures in the 26·68 day solar magnetic period, by Frank H. Bigelow. The northern low-pressure and the southern high-pressure belts of North America vary in latitude directly with the solar magnetic intensity, being further north at the maximum and further south at the minimum of the period; whilst the northern high and southern low-pressure belts vary in the opposite manner. This means that an increase of solar magnetic intensity generates the cyclones further south, and causes the anti-cyclones from the polar circulation to travel to the south.—Remarks on colloidal silver, by C. Barus. Colloidal silver possesses properties which can be explained with reference to the analogous behaviour of suspended sediments, allowance being made for differences in the size of particles. The high degree of insulation detected in Carey Lea's metallic mirrors may be interpreted as an instance of the altered behaviour of non-coherent metallic matter.—Resonance analysis of alternating currents, by M. I. Pupin. Part ii. Closed magnetic circuit transformers distort the primary current considerably more than transformers with open magnetic circuits under equal degrees of magnetisation. A ferric self-inductance in circuit with an alternator which gives a simple harmonic E.M.F. distorts the current by introducing higher odd harmonics, principally the harmonic of three times the frequency of the fundamental. Rotary magnetic fields produced by reasonably well-constructed machines are not accompanied by fluctuations in their intensity.—An improved form of interruptor for large induction coils, by F. L. O. Wadsworth. The interruptor consists of a brass wheel about six inches in diameter, with two insulating and two contact segments placed in its circumference, and mounted directly on the shaft of a small electric motor making about 1200 revolutions per minute. Two copper brushes are made to bear on the hub of the wheel and its circumference respectively. The hub and the conducting sectors are in one piece. The insulators are made of slate.

Wiedemann's Annalen der Physik und Chemie, No. 12.—On the measurement of surface tension of water in capillary tubes of different glasses, by P. Volkmann. A good wetting capacity may be insured by soaking the glass tubes in caustic potash, and then washing with distilled water. That the tubes are perfectly wetted is shown by the perfect mobility of the line of contact. The more nearly circular the section of a tube is, the more does the value of the surface tension of water approach 7·38 mg/mm. at 20·2° C., whatever the kind of glass. Tubes of very small diameter give larger values.—On the thermochemical processes in the secondary cell, by Franz Streintz. The following thermochemical equations were derived from the author's experiments:

$$PbO_2 + H_2SO_4 \text{ aq} = PbSO_4 + \text{Aq} + 767 \text{ K}$$
$$PbO_2 + SO_2 \text{ gas} = PbSO_4 + 844 \text{ K}$$
$$PbO_2 + H_2 \text{ gas} = PbO + H_2O + 583 \text{ K}$$
$$PbO_2 = PbO + O \text{ gas} - 101 \text{ K}$$

The E.M.F. resulting from these equations is 1·885 volts. One o the cells worked with, that having the least concentration, gave 1·90 volts.—On the magnetisation of iron and nickel wires by rapid electric oscillations, by Ignaz Klemencic. The strong damping action of magnetisable metals upon electric oscillation is explained by their circular or transverse magnetisation, which crowds the oscillations into the surface layers much more than in the case of other metals. Hence the resistance of a magnetisable wire to electric oscillations is much greater than that of another of equal conductivity. This resistance was determined by studying the development of heat in the wire by means of a thermo couple. The permeabilities of the metals deduced by the formulæ of Lord Rayleigh and Stefan were: Soft iron, 118; steel pianoforte wire, soft 106, hard 115; Bessemer steel, soft 77, hard 74; nickel, 27. These are very near the values found by Baur and Lord Rayleigh for feeble magnetising fields.—Studies of the electric resonator, by P. Drude. The author shows that a Hertzian resonator must be chiefly affected by the electric forces playing at that part of the resonator circuit which lies opposite the gap, and proves this experimentally. The resistance of a Zehnder vacuum tube used in these experiments was incidentally found to be 2870 million ohms when the interruptor made 25 breaks per second.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, December 5.—Capt. H. J. Elwes, President, in the chair.—Mr. F. Merrifield exhibited hybrids belonging to the genus *Saturnia*, obtained by Dr. Standfuss, of Zürich; viz. a male and female hybrid from a male of *Saturnia pavonia* and a female of *Saturnia pyri*, to which he had given the name of *Saturnia emiliæ*; also hybrids from what Dr. Standfuss described as "a male of *Callimorpha dominula*, var. *persona*" (received from Tuscany) and a typical female of *Callimorpha dominula*, to which he had given the name of *romanovi*. Mr. Merrifield remarked that the so-called var. *persona* differed entirely from the type of *Callimorpha dominula*.—Mr. J. W. Tutt exhibited, and read notes on, specimens of a very small form of *Euchloë*, taken in Shropshire by the Rev. F. B. Newnham, who was of opinion that it was distinct from *E. cardamines*. He pointed out that it was much smaller than the latter species, and that the discoidal spot was placed as in *E. turritis* and *E. gruneri* at the juncture of the orange and white spaces, and not, as in *E. cardamines*, well within the orange tip. Mr. Tutt also exhibited, and read notes on, specimens of *Noctua dahlii*, from Cheshire, Essex, Yorkshire, Aberdeenshire, and other counties. The variation in the specimens was said to be partly due to their geographical distribution. Herr Jacoby read a letter received from Mr. Buxton Forman, one of the Assistant Secretaries of the Post Office, to the effect that the Postal Union had decided to make a rule not to allow natural history specimens to be sent by sample post, which was intended for the transmission of *bonâ fide* trade patterns or samples of merchandise, and consequently that the forwarding of such specimens at the sample rate would in future be irregular. Lord Walsingham, F.R.S., stated that he had had a long correspondence with the Post Office authorities on the subject, and that the late Mr. Raikes, when Postmaster-General, promised him in 1891 that such specimens should, so far as the British Post Office was concerned, be transmitted at the sample rates; and a letter to the same effect, from the late Sir Arthur Blackwood, when Secretary of the Post Office, was published in the *Proceedings* of the Society for 1891.—Mr. C. G. Barrett exhibited, for Mr. A. J. Hodges, a specimen of *Hydrilla palustris*, from Wicken Fen, also specimens of *Caradrina ambigua*, from the Isle of Wight. He remarked that one specimen of the latter had the hind margin of the right fore-wing indented, and the wing broadened as though from an injury to the pupa. In this wing the margins of the large orbicular and reniform stigmata had become so joined that the dividing lines had disappeared, and the stigmata were fused into one irregular blotch.—Mr. McLachlan, F.R.S., exhibited, on behalf of Mr. G. F. Wilson, F.R.S., a "grease band" which had been tied round trees to prevent the females of *Cheimatobia brumata* from ascending the trunks for the purposes of oviposition; the band was thickly covered with the bodies of the females, together with a few males.—Surgeon-Captain Manders exhibited a pair of *Chelura bifasciata*, from the Shan States, and called attention to the "assembling" habits of the males, some hundreds of which were attracted by the numerous females which emerged from the cocoons at sunset.—Mr. B. A. Bower exhibited a beautiful variety of *Zygæna lonicerœ*, Esp., having the spots confluent, taken at Chattenden Wood, North Kent, in June last.—Mr. H. Goss exhibited, for Mr. F. W. Urich, of Trinidad, a series of males, females, and workers of *Sericomyrmex opacus*, Mayr., a species of fungus-growing and fungus-eating ant.—Colonel Swinhoe read a paper entitled "A List of the *Lepidoptera* of the Khasia Hills, Part III."—Mr. C. J. Gahan read a paper entitled "On the Longicorn *Coleoptera* of the West India Islands."—Mr. F. W. Urich communicated a paper entitled "Notes on the Fungus Growing and Eating Habit of *Sericomyrmex opacus*, Mayr."—Prof. E. B. Poulton, F.R.S., read a paper, by Prof. E. B. Titchener, entitled "An apparent case of Sexual Preference in a male Insect."—The Rev. H. S. Gorham communicated a paper entitled "Notes on Herr A. Kuwert's Revision der Cleriden-gattung *Omadius*, Lap."

Geological Society, December 5.—Dr. Henry Woodward, F.R.S., President, in the chair.—Supplementary note on the Narborough district (Leicestershire), by Prof. T. G. Bonney, F.R.S.—The tarns of Lakeland, by J. E. Marr, F.R.S. The author had examined several tarns of the English Lake district.

In those cases where the stream issues from the tarn over solid rock, he found either (1) direct evidence that the tarn results from the blocking up of part of a pre-existing valley by drift, causing the deflection of the water to a direction different from that of the original stream in this locality; or (2) evidence which is perfectly consistent with such an explanation of the origin of the tarn. Under the circumstances he submitted that tarns cannot be assumed to lie in rock-basins simply because the issuing stream flows over solid rock (and this assumption has been made), but that those who maintain the existence of such rock-basins must prove the occurrence of solid rock entirely around the tarn.—Description of a new instrument for surveying by the aid of photography, with some observations upon the applicability of the instrument to geological purposes, by J. Bridges Lee. The instrument described in this paper consists essentially of a photographic camera fitted inside with a magnetic needle, which carries a vertical transparent scale divided and numbered to 360°, and also with cross fibres which intersect at right angles. The fittings and adjustments of the instrument are of such a character that the camera can be accurately levelled and directed towards any point in a horizontal direction, and when a photograph is taken in an ordinary way the bearing of the median vertical plane which bisects the instrument through the photographic lens will be recorded automatically on the face of the photograph. The vertical fibre (and its image on the photograph) serves as an index to read the bearing; and the same fibre marks by its shadow a line right across the photograph, which marks the median vertical plane on the image. The horizontal fibre is adjusted to mark on the image the horizontal plane which bisects the photographic lens.—The marble beds of Natal, by David Draper.

Royal Microscopical Society, November 21.—Mr. A. D. Michael, President, in the chair.—Messrs. Swift exhibited and described a microtome, which was made as an improvement on the Cambridge rocking microtome. The chief features were that the razor could be fitted at any angle that might be found best suited to the substance it was desired to cut, that it was possible to cut sections embedded in celloidin in spirit, and that it could be used with the ether-freezing apparatus. Messrs. Swift also exhibited an improved example of their new mechanical stage. The milled heads of the stage were now placed on the same side; the stage had also a greater lateral movement than in the first examples.—Dr. Measures exhibited a new mechanical stage by Messrs. Zeiss. He considered that it would be found to be better protected than the old one, and it would admit a much larger plate. It was also fitted with verniers in both directions reading to $\frac{1}{10}$ of a millimetre.—Dr. W. A. Turner gave a lantern demonstration on recent methods of staining sections of the central nervous system.—Mr. E. M. Nelson described a simple method for measuring the refractive indices of media. He also described a new reflecting camera lucida, and a portable microscope by Zentmayer.

Zoological Society, December 4.—Henry Seebohm, Vice-President, in the chair.—A communication was read from Mr. T. Manners Smith, on some points in the anatomy of the water-mole (*Ornithorhynchus paradoxus*). The paper related chiefly to the muscular anatomy of *Ornithorhynchus*, which was followed by a short description of the trunk-arterial system. As regards the anatomy, Mr. Smith appeared to have worked out for the first time the comparative morphology of the skeletal muscles of the Monotremes as determined by their innervation.—Mr. F. E. Beddard, F.R.S., read a paper upon certain points in the visceral anatomy of *Ornithorhynchus*. The paper dwelt in the first instance with the existence of a free fold passing from the bladder to the liver, where it became continuous with the falciform ligament of the liver. This fold, however, exhibited no traces of an anterior abdominal vein. The author also gave a description of the right auriculo-ventricular valve of the heart. In two hearts examined by him the septal flap of this valve was complete, though less conspicuous than the free flap, owing to the fact that it had either no papillary muscles attached to it, or that the muscles were very small. Mr. Boulenger read a second report on additions to the Lizard Collection in the Natural History Museum.—Prof. F. Jeffrey Bell called attention to the acquisition by the Natural History Museum of some specimens of remarkable corals of great size from North-west Australia, of which he showed some admirable photographs taken by Mr. Percy Highley. Prof. Bell urged the necessity of the acquisition of large specimens of corals, before coming to any conclusion as to their specific distinctions.

PARIS.

Academy of Sciences, December 10.—M. Lœwy in the chair.—The Secretary announced the death of M. Tchébichef, foreign associate, on December 8.—The decease of M. Ferdinand de Lesseps, on December 7, was referred to by the President, and the meeting adjourned, after receiving the correspondence, as a mark of respect for the deceased member.—A study of the different varieties of graphite, by M. Henri Moissan. Any variety of carbon may be converted into graphite by sufficiently raising the temperature. This graphite may be amorphous or crystalline. Its specific gravity varies from 2·10 to 2·25. Its ignition point in oxygen is about 660°. Its stability, as evidenced by its resistance to transformation into graphitic acid, depends on the temperature to which it has been raised.—A survey made by means of photography, for the delimitation of the frontier between Alaska and British Columbia, by M. Laussedat.—On the secular variations of the orbits of the four interior planets, by Prof. S. Newcomb. (See "Our Astronomical Column.")—On a new ossiferous cavern discovered at Pointe-Pescade, to the west of Alger-Saint-Eugène, by M. A. Pomel. There appears to be no trace of man or of the monkey, though numerous other species of animals are represented in the remains.—On the solution of numerical equations by means of recurrent series, by M. R. Perrin.—On the composition of linear forms and congruences, by M. Stouff.—On elimination, by M. Hadamard.—On the law of resistance of air, by M. C. Chapel. A claim to priority over M. Vallier in regard to the empirical laws recently enunciated by the latter.—An experimental theory of the clipping and punching of metals, by M. Ch. Fremont. A machine is described with which the author has succeeded in registering the work done during punching operations on an indicator diagram.—Integration of the equations of light in transparent and isotropic media, by M. E. Carvallo.—Electromotive force of magnetisation, by M. D. Hurmuzescu.—Determination of the proportions of carbonate of lime and carbonate of magnesia in earths, ashes, &c., by M. Albert Trubert. A description of a simple indirect analysis.—The phosphate of the Grande Connétable, by M. A. Andouard.—On pectase and pectic fermentation, by MM. G. Bertrand and A. Mallèvre. The conclusions have been arrived at, that (1) this ferment is not able to coagulate pectin when acting alone; (2) it produces this transformation only in presence of salts of calcium, barium, or strontium; (3) the precipitate produced is an alkaline-earthy pectate.—On a new process for the purification of alcohols, sugars, and a certain number of other organic matters, by M. E. Maumené.—Influence of radiation at low temperatures on the phenomena of digestion; Frigotherapeutics, by M. Raoul Pictet.—On the morphology and classification of the Coccidians, by M. Alphonse Labbé.—Succession of the lower Tertiary strata in the cretaceous protuberance of Saint-Sever, by M. L. Reyt.—On the *calcaires à lithothamnium* of the valley of the Chellif, by M. Repelin.—Influence of the dryness of the year 1893 on the forest vegetation in Lorraine, by M. Henry. The production of wood for 1893 was but 30 to 76 per cent. of the normal yield.—The ascension of the balloon *Archimède* (October 11, 1894). Comparative thermometric and hygrometric diagrams of the aerostat gas and the surrounding atmosphere, by MM. Gustave Hermite and Georges Besançon.

BERLIN.

Physical Society, November 16.—Prof. von Bezold, President, in the chair.—Prof. H. W. Vogel spoke on the perception of colours, and demonstrated the various effects which monochromatic illumination has on a series of pigments. The effect of two coloured lights on the several pigments was specially interesting. Thus, for instance, red or yellow squares illuminated by yellow and red light appeared to be white and grey; under yellow and blue they appeared to be red, and in yellow and green lights they appeared the same as when illuminated by white light. Dr. Rubens gave an account of experiments carried out on a large scale in conjunction with W. and E. Rathenau on telegraphing to a distance without wires. They were based, in contradistinction to those of Preece, on the principle of the distribution of currents in the conducting earth. On the banks of the Wannsee, near Potsdam, two electrodes were sunk in the water at a distance from each other of 500 metres, and a current from fifty-five accumulators placed on the bank was sent through them. From each of two boats connected by a cable an electrode was immersed in the water, and a telephone inserted into the connection. When the current from the accumulators on the bank was broken, this produced an effect on the telephone audible at a distance of 4·5 kilometres. Small islands lying between the shore and the boats had no influence on the transmission of the signals.

Meteorological Society, November 6.—Prof. Hellmann, President, in the chair.—Dr. Meinardus spoke on sheet-lightning and the various theories in explanation of this phenomenon. He sided with the view that it is due to a thunderstorm of which the lightning is visible, whereas the thunder does not reach the observer owing to total reflection brought about by refraction in the several superimposed layers of air.—Prof. von Danckelman spoke on the climate of Jalu, on the basis of observations made by Dr. Steinbach since the beginning of 1893 with accurate self-registering instruments. Among the peculiarities of the climate, which is continuously and uniformly warm and moist, it is more especially remarkable that thunderstorms and heavy rainstorms occur most usually between 9 and 10 o'clock in the morning. This phenomenon has not as yet been observed anywhere else.

Physiological Society, November 9.—Prof. du Bois Reymond, President, in the chair.—Dr. Levy-Dorn spoke on the effect of various temperatures on the secretion of sweat, and communicated the results of his own experiments on cats, dealing with the secretion of sweat at low temperatures. The sweat glands themselves were kept at the temperature (19°–30° C.) most favourable for the secretion, while the animal's body was cooled by water at 6° C., and secretion was obtained as a result of dyspnœa, notwithstanding the cooling of the body. The same speaker further gave an account of experiments made with a view to testing Prof. Grützner's assertion that heat acts only on centripetal and vasomotor nerves, but does not affect motor or centrifugal nerves. Carefully observing all the experimental conditions described by Grützner, he had found that the action of heat on the sciatic nerve leads to a copious secretion of sweat on the cat's paws, that is to say, stimulates centrifugal nerves.—Prof. Zuntz criticised the objections raised by Bohr and Henriquez against his experiments on the measurement of the work done by the heart, and showed up the errors which had crept into their observations. He next demonstrated the apparatus he had employed for measuring the amount of blood forced out by the heart.

NEW SOUTH WALES.

Linnean Society, October 31.—Prof. Haswell, Vice-President, in the chair.—Notes of a visit to the island of Erromanga, New Hebrides, in May 1894, by Sutherland Sinclair.—Preliminary communications on the cerebral commissures of the mammalia, with special reference to Monotremata and Marsupialia, by G. Elliott Smith. From an examination of the brain in platypus, *Echidna*, *Perameles*, kangaroo, wallaby, kangaroo rat, *Dasyurus* and phalangista, the superior commissure of the cerebrum was shown by the author to be homologous with the psalterium of Placentalia, and not with the corpus callosum. There appears to be no true corpus callosum (as distinct from a psalterium) in any monotreme or marsupial. The hook-like appearance of the hippocampal commissure in sagittal section in marsupials, which led Flower to regard it as corpus callosum, was said to correspond to the shape of the hippocampus, which is co-extensive with the lateral ventricle. In platypus only the dorsal limb of the hook is present, because there is only a rudimentary descending horn of the ventricle and hippocampus. In Eutheria only the ventral limb persists, because the upper and anterior part of the hippocampus disappears to allow a corpus callosum to appear in the situation occupied by the dorsal limb of the hippocampal commissure in Metatheria, *i.e.* ventral to the arcus marginalis. The fascia dentata, as a consequence of this, is essentially *supracollosal*. A doubt was expressed as to the presence of any structure in the submammalia strictly homologous to the Eutherian corpus callosum. The hypothesis was advanced that the latter structure appears (just as the hippocampal commissure does somewhat earlier) to supply the demand for a shorter connecting path for the great pallial development—essentially a mammalian feature.—Descriptions of some new species of Australian Coleoptera, by A. M. Lea. Descriptions were given of forty-nine species from New South Wales, mostly belonging to the *Anthicidæ*. A remarkable *Protopalus* from the Tweed River was described, and a species of *Lagria* living in ants' nests.—Description of a new *Isopogon* from New South Wales, by R. T. Baker. The *Isopogon* described was obtained on the Murrumbo Ranges, Goulburn River. It differs from the N.S.W. *I. anemonifolius* in having deeply-divided leaves on long petioles and a silky hairy perianth; from the West Australian *I. longifolius* in its longer and pinnately divided leaves, smaller cones and longer perianth.—Synonymy of some Australian and Tasmanian mollusca, by John Brazier. The synonymy of twelve species were given with references and habitats.—Further observations upon the anatomy of the integumentary structures in the muzzle of *Ornithorhynchus*, by Prof. J. T. Wilson and C. J. Martin. The authors specially dealt with the details of structure of the "push-rods" in the skin of the snout of the platypus, and offered further confirmation of their views in opposition to a recent criticism of some of these by Prof. E. B. Poulton.—Description of the external characters of a very young specimen of *Ornithorhynchus*, by Prof. J. T. Wilson.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—University Tutorial Series, Vol. 1: A Text-book of Sound: E. Catchpool (Clive).—Manual of Practical Morbid Anatomy: Drs. Rolleston and Kanthack (Cambridge University Press).—The Book of the Rose: Rev. A. Foster-Melliar (Macmillan).—An Elementary Treatise on Theoretical Mechanics, Part 3: Kinetics: Prof. A. Ziwet (Macmillan).—Natural Rights: Prof. D. G. Ritchie (Sonnenschein).—Elementary Qualitative Chemical Analysis: Dr. F. Clowes and J. B. Coleman (Churchill).—Pubblicazioni della Specola Vaticana, Vol. iv. (Torino, Artigianelli).—A Few Chapters in Astronomy: C. Kennedy (Taylor and Francis).

PAMPHLETS.—On the Natural Immunity against Cholera, &c.: C. G. Gümpel (Williams and Norgate).—Elliptical Orbits: H. Larkin (Unwin).—Royal Gardens, Kew, Hand-list of Trees and Shrubs grown in Arboretum, Part 1: Polypetalæ (Eyre and Spottiswoode).

SERIALS.—Engineering Magazine, December (Tucker).—American Journal of Science, December (New Haven).—Strand Magazine, December (Newnes).—Natural History Transactions of Northumberland, &c., Vol. xi. Part 2 (Williams and Norgate).—Verhandlungen des Naturhistorischen Vereins der Preussischen Rheinlande, &c., Einundfünfzigster Jahrgang, Sechste Folge. L. Jahrgang. Erste Hälfte (Bonn, Cohen).—Medical Magazine, December (Strand).—Le Monde Moderne, January (Paris).—American Naturalist, December (Wesley).—Strand Musical Magazine, No. 1 (Newnes).—Royal Natural History, Part 14 (Warne).

CONTENTS.

THURSDAY, DECEMBER 27, 1894.

A STANDARD TREATISE ON CHEMISTRY.

A Treatise on Chemistry. By Sir H. E. Roscoe, F.R.S., and C. Schorlemmer, F.R.S. Vol. I. "The Non-Metallic Elements." New edition, completely revised by Sir H. E. Roscoe, assisted by Drs. H. G. Colman and A. Harden. Pp. xi. 888. (London: Macmillan and Co., 1894).

TO write a satisfactory review of this book is no easy task. The word which shall express an appreciation and a criticism does not come readily to one's pen. Turning over the pages and reading the lucid descriptions of preparations and properties of element after element, and compound following compound, one is depressed, and borne down by the burden of many facts and much learning. But to this depression succeed the pleasure and the sense of power that belong to the gaining of knowledge, and the feeling of security that remains with the man who has got down to fundamental facts.

In the preface to the first edition of this "Treatise," the authors said:

"It has been the aim of the authors . . . to place before the reader a fairly complete, and yet a clear and succinct, statement of the facts of modern chemistry, whilst at the same time entering so far into a discussion of chemical theory as the size of the work and the present transition state of the science permit."

In his preface to the present edition, Sir Henry Roscoe says:

"In this new, completely revised and reprinted, edition I have endeavoured to carry out the aims which were put forward in the preceding preface seventeen years ago."

The aim and scope of the work are made evident by these extracts from the prefaces. There can be no doubt that the authors succeed in giving "a fairly complete, and yet a clear and succinct, statement of the facts of modern chemistry." The descriptions of the properties of elements and compounds are lucid, full, and accurate; where all the properties of a substance cannot be described, the selection made is satisfactory, sometimes, one may suppose a student to say, too satisfying. But this even flow of excellent description does not inspire with enthusiasm him who reads; it does not open up glimpses of the unexplored regions; it fails to stir the emotions. The book is wanting in the charm that accompanies the "twilight of dubiety."

It is difficult always to agree with the authors in their estimate of the relative importance of chemical facts. The most important fact of modern chemistry I take to be the statement that "the properties of the elements and compounds, and the compositions of compounds, vary periodically with the atomic weights of the elements." This fact ought, I think, to be made the basis of every treatise on descriptive chemistry; because only by doing this can the facts regarding individual substances appear in right perspective. The great fact which we owe to the genius of Mendeléeff will find expression in a later volume of this "Treatise" (see p. 53); but the student who uses the book will then probably have arranged the intellectual contents of his mind, so far as chemistry is concerned, in many little parcels, each tied up separately, and he will find much difficulty in untying the parcels, arranging their contents afresh, and getting them all within the compass of the one binding generalisation.

As regards the statements of the properties of the different non-metallic elements and their chief compounds, no detailed appreciation is called for. Where all is excellent, a general expression of praise is sufficient. The chapters wherein are described hydrogen, fluorine, oxygen, sulphur, nitrogen, and the other non-metals, and the principal compounds which these element form by combining with one another, contain all that - student of chemistry requires to know about these elements and compounds, except the comparison and contrast—that is to say, the classification—of the substances described The student has presented to him, in this volume of the "Treatise," the material that is needed for acquiring a real knowledge of the chemistry of the non-metallic elements.

Some of the expressions, and the ways of putting descriptive facts, might be improved, in my opinion.

"Hydrogen occurs almost solely in a state of combination in nature" (p. 129).

"In a state of combination hydrogen occurs in water" (p. 129).

"Bromine does not occur in the free state in nature" (p. 188).

Expressions like these seem to me to be survivals from the alchemical times, when, to take an example, nitric acid was looked on as water endowed with acidic qualities, which could be removed or restored at pleasure, and hence was called *aqua fortis*. Surely it is not hydrogen that occurs "in a state of combination," but compounds of hydrogen that occur in nature. Similarly if bromine occurs at all it must be "in the free state," else it would not be bromine but something else. Each compound of hydrogen, and each compound of bromine is just as definitely a chemical individual as hydrogen, or bromine, itself.

I do not think that the object of chemistry, namely the study of the connexions between changes of composition and changes of properties, is set forth with sufficient clearness. The statement on pp. 51, 52, for instance, that

"the science of chemistry has for its aim the experimental examination of the elements and their compounds, and the investigation of the laws of their combination one with another,"

cannot be regarded as satisfactory. On the other hand, the examples given of chemical action, in the pages preceding that where the sentence just quoted occurs, undoubtedly serve to keep before the student the fundamental fact that change is the essential note of all chemical occurrences.

The term *density* is sometimes applied to gases in a way that is confusing. For instance, on p. 160 the term is applied to the relative density of chlorine, referred to hydrogen as unity, and also referred to air as unity, without an indication that the unit has been changed.

A feature of the book which is much to be commended is the giving of the definite experimental data from which important conclusions are deduced. A good example of this is seen in the authors' treatment of the eudiometric synthesis of water (pp. 246–250). The actual details of an experiment are given, with the experimentally determined data, and the conclusion to be drawn is then stated. It is much to be regretted that the authors do not quote the results obtained by Scott regarding the volumes of hydrogen and oxygen which combine to form water, but content themselves with the less recent, and certainly less accurate, measurements made by Morley (p. 251).

The authors would have done well to have followed their own practice elsewhere, and to have given moderately complete details of the methods, and the data, whereby the atomic weight of each element has been determined. In describing the electrolysis of dilute sulphuric acid solution (pp. 45, 129, 251), the authors might have more clearly insisted on the fact that the electric current is employed to set free hydrogen and oxygen from an aqueous solution of sulphuric acid, and that they had not, following it is true almost every other text-book, spoken of the phenomena as the electrolysis of *water*.

Chemical equations convey, at the best, only a small portion of the information one wishes to have regarding chemical occurrences; but, by the simple devices of using three kinds of type, and adopting a symbol to represent an aqueous solution of a substance, these equations may be made to tell much more than is conveyed to the reader by the equations used in this "Treatise."

In the extract from their preface already quoted, the authors say that they enter into "a discussion of chemical theory so far as the size of the work and the transition state of the science permit." The subject-matter of chemistry is so large, and the difficulties of bringing the vast array of facts into a focus are so great, that the science is likely to continue for a long time in a transition state, and the principles of chemistry to continue to be, as they are at present, rather a number of somewhat loosely attached hypotheses than an harmonious and binding theory. Nevertheless, more unity might profitably have been given to the chapter on the "General Principles of the Science." Many portions of this chapter are admirable; the whole of it is characterised by lucidity. The portions dealing with the laws of combination and the Daltonian atomic theory are especially excellent. Brief but very clear accounts are given of the experimental methods for determining molecular weights, including the methods which are based on van't Hoff's extension to dilute solutions of the law of Avogadro. In connexion with the molecular condition of substances in solution, there is a deliciously airy note (p. 111): "For the literature of this subject the volumes of the *Zeitschrift für Physikalische Chemie* . . . may be consulted." The student who proceeds, with a light heart, to consult the journal in question will find he has his work cut out for him.

The book, taken as a whole, is admirable. The sure position that the earlier editions of the "Treatise" have taken in chemical literature has shown how much the work was wanted, and how cordially it has been welcomed by chemists. It is sufficient to say that this, the first volume of the revised edition, well maintains the reputation of the original "Roscoe and Schorlemmer."

M. M. PATTISON MUIR.

MAN—THE PRIMEVAL SAVAGE.

Man—the Primeval Savage. By Worthington G Smith. (London: Stanford, 1894.)

MR. WORTHINGTON SMITH has devoted himself for many years to a study of the localities near London where implements have been found, and has described the various palæolithic floors with great minuteness, and illustrated them with great artistic skill. In this book he brings all his previous discoveries together, and groups them round his last work at Caddington, near Dunstable, on the borders of Hertfordshire and Bedfordshire. He has presented to us a monograph on palæolithic camping-places, rather than a general treatise on Man, the Primeval Savage.

The palæolithic floor at Caddington was buried under a depth of clay, sand and gravel, amounting in some places to thirteen feet from the surface. The strata occur in the following order from the surface: (1) Contorted drift; (2) reddish-brown clay, with implements stained with red ochre; (3) subangular gravel with ochreous implements, slightly worn and battered; (4) white clay; (5) gravel, with white unworn implements; (6) reddish-brown clay with implements; (7) clayey gravel with implements; (8) clayey brick-earth; (9) palæolithic floor resting on a clayey brick-earth similar to that above it. All these deposits form a thickness about eight feet in this section, and belong to the complicated series of superficial sand clays and gravels grouped together by the Geological Survey as brick-earth, and clay-with-flints, and which are clearly proved to be later than the boulder-clay of the district. The interest chiefly centres in the palæolithic floor No. 9, resting upon a sun-cracked surface in some places, and in others supporting heaps of flints carefully selected, and evidently piled together for the purposes of implement-making. Around them lay worked flints by the thousand. It is obvious that here we are on the track of a palæolithic camping-ground, and that the deposits which now cover it up have been accumulated, the fine clays by heavy rains on the margin of a stream or on the borders of a lake, and the sands and gravels by the natural drift of the soil downwards from a higher level. The distribution also of the flint implements in the section, prove that man inhabited the district while the strata were being accumulated above the palæolithic floor up to No. 2 inclusive. As the mud accumulated on the old floor, the hunters, attracted probably by the water close at hand, visited the same spot from time to time, and left their implements in 7, 6, and 5 of the section. These, our author considers to be the same age as those of the palæolithic floor. The worn ochreous implements in Nos. 2 and 3, he relegates to a later time in the palæolithic age, and considers them to have drifted downwards from a higher level into their present position. "The water must have drained elevations which have now vanished, and the hill-tops of the Dunstable district of the present time must represent the valleys of the old time." Caddington is now on the water-parting between the sources of the Lea and the Ver, and under present conditions there is no higher ground from which these materials could have been derived.

The worked flints on the palæolithic floor represent every stage of manufacture, from the unshaped block to the finished *hâche*. There are the flint cores and the flakes lying beside them, there are flint hammer-stones and anvils, punches and scrapers, and other implements broken in various stages of manufacture. Very few of the latter are finished. They would, of course, be carried off for use, as was the case with those of the palæolithic floor discovered some ten years ago, in the brickpit at Crayford, by Mr. Flaxman Spurrell. Mr. Smith, we may remark, has followed the example of the latter, in the infinite pains he has taken to build up the original forms of the flint blocks from the broken implements and splinters. It is clear that in this place we have the workshop in the condition in which it was left by the palæolithic hunter. The fact that no bones and no charcoal have been discovered, shows that the palæolithic huts were some little distance away, and that this spot was selected solely for the purpose of implement-making.

The association of the ruder with the more finished of the palæolithic implements in this floor, as in the case of many of the palæolithic caverns, proves that an appeal to rudeness of form as a test of age, is a wrong principle. That man must have learnt first of all to make the simpler before he made the more complex implements, is so obvious, that it has never been disputed. The ruder, however, were used side by side with the more finished, and many of those forms which are taken to be of pre-palæolithic age in the gravels of the Kentish plateau are the necessary result of the working of the flint block into the palæolithic *hâche*. We may remark, further, that some of these are also found in the refuse-heaps round the old flint-mines of Cissbury, and have been made in the manufacture of neolithic implements.

In the introduction, Mr. Smith deals with the general question of the relation of palæolithic man to the glacial period, and concludes, rightly in our opinion, that man inhabited south-eastern England after the glacial period. We also agree with him in looking at the pre-glacial or post-glacial age of man as merely of local significance, because the glacial period is a purely local phenomenon not marked in the warmer southern lands, such as the Indian peninsula, which was inhabited by the palæolithic hunter. We know of him in India simply as living in the pleistocene age. He probably invaded Europe in the pre-glacial age, and lived in the south while Britain lay buried under a mass of glaciers, or was covered by a berg-laden sea. He is post-glacial in the valley of the Thames. He is not separated from our own times either by a wall of ice—one of the ice periods of Prof. James Geikie—or by the tumultuous waters of a vast deluge, such as that recently put before us by Sir Henry Howorth. He is separated by a geographical revolution during which the seaboard of north-western Europe, as we find it now, came into being, and Britain became an island—as well as by a change in our land from a continental to an insular climate.

The author also touches the difficult problem of the physique of primeval man, and he accepts the "type de Canstadt" as the earliest palæolithic race. This is, however, founded on a human skull which M. d'Acy has conclusively proved to have no claim to any definite age. According to the evidence of the catalogue, still preserved, of the pleistocene mammalia found at Canstadt in 1700, it was not found along with them. Dr. Reissel, who superintended the exploration for the Duke of Würtemberg, wrote in 1701 that no human remains were then found, "inter quæ tamen nulla humanis possunt comparari." Some fifty years later Dr. Albrecht Gessner, writing on the discovery, remarks that it is strange that no human remains had been met with. Both these were doctors to the Dukes of Würtemberg, and can only be supposed to know a human skull when they saw it. It was not until 1835 that the skull in question was found by Dr. Jaeger, in the Museum at Stuttgart, and assigned without proof of any kind to the find made 135 years before. It is very unfortunate that such faulty evidence as this should not only be accepted by the authors of "Crania Ethnica," but also used for the definition of the type "de la plus vieille des races humaines." In the present unsatisfactory state of the inquiry into the physique of palæolithic man, the only safe course is to subject all the facts which have been recorded to the most searching criticism, and to wait for the further light which will come sooner or later from new discoveries. In this small and well-illustrated monograph, Mr. Smith has made our knowledge of the palæolithic workshop more definite than it was before, and has collected together a mass of information which will be of great service to the archæologists of London.

W. BOYD DAWKINS.

THE SEQUENCE OF STUDIES.

Physiology for Beginners. By Professor M. Foster, M.A., M.D., F.R.S., and Lewis E. Shore, M.A., M.D. (London: Macmillan and Co., 1894.)

Outlines of Biology. By P. Chalmers Mitchell, M.A., F.Z.S. (London: Methuen and Co., 1894.)

Practical Methods in Microscopy. By C. H. Clark A.M. (Boston: Heath and Co., 1894.)

THE scientific precision and modernness of a book of elementary physiology, written by Dr. Shore, under the supervision of Prof. Foster, is scarcely to be called in question. This little volume is amply illustrated, and written with clearness as well as exactness. The authors are especially to be commended for laying stress in their preface upon the necessity of a preliminary acquaintance with Chemistry and Physics, and it is to be regretted that they had not the courage to insist upon this point. But here they are gravely open to criticism. "Knowing," they say, "how frequently a book on physiology is taken up without any such previous acquaintance, we have given a few chemical and physical facts as preliminaries in chapter i." A few, and quite too few, it is—six complete pages—expanding scarcely any of the principles which are involved in the simplest physiological explanation, giving, of course, no conceptions of the relations of chemical combination to energy, nor of osmose, diffusion, solution, isomerism, nor the action of ferments, all of which come to the front directly one approaches respiration or digestion. We cannot but think that this concession to a common educational error is greatly to be deplored. The authors occupy a position of authority, and it was their privilege—a privilege they have neglected—to demand here, by assuming a sound basis of chemical and physical knowledge, the proper sequence of studies. As it is they have produced a little primer that by virtue of its clearness and attractiveness and the prestige of their names, will serve to uphold for a few years longer a fundamentally faulty system of scientific education.

The evil of a neglect of the rational sequence of studies becomes particularly apparent in the chapters upon the eye and ear. In the former of these an attempt is made to convey all the optical principles involved, in seven lines—"convex lens" is not even defined—and in the latter comes a series of dogmatic statements about sounds and noises, without a particle of that progressive reasoning process which is the very essence of genuine scientific study. Once the initial concession was made, however, this kind of thing was an inevitable consequence. In order to explain the science in hand, three or four others have to be compressed to the limits of a paragraph.

The same unfortunate disposition to begin the wrong way about is apparent in the little book by Mr. Chalmers Mitchell. But in his case there is even less excuse. His book is designed to prepare students for the Conjoint Boards Examination, and therein he is an examiner. Since he calls the tune he might have danced as he liked, and he has, we conclude, preferred of his own free will to contravene the common-places of educational science. We find such a proposition as the following, printed in spaced type; so that the medical student, preparing for examination by Mr. Chalmers Mitchell, who fails to learn it by heart will have only himself to blame for his failure. The earthworm, we are told,

"has reached the second stage of cœlomate development in that it is very highly segmented, and there is little or no trace of the third stage, the stage of the condensation of segments." . . . "Vertebrates are highly segmented animals, in which condensation of segments has become an important factor, resulting notably in the formation of a complicated head, and of kidneys formed by the aggregation of many nephridia."

Now these propositions are illustrated rather than supported by a brief description of the anatomy of the earthworm, dogfish, and frog, and we find that even in the case of these types the metameric segmentation of the cranial nerves is scarcely alluded to, and the homology of the mandibular arch with the branchial bars is not presented as a probability, but stated as a fact. And, in brief, Mr. Chalmers Mitchell, who is not a crammer, but a teacher, gives the medical student the impression almost in so many words—"cut and dried" and ready to be cast into the oven—that the vertebrate type is merely a concentrated derivative (concertina fashion) of the chætopod type, advancing this pure, and as he gives it, baseless, speculation, in the face of the absence of any chætopod stage in the embryology or palæontology of the vertebrates, in the face of the lesser metamerism in the vertebral column of more primitive fishes, and in the face of the declared opinion of many prominent anatomists. But whether the view he gives is right or wrong is, from our point of view, the smaller issue; the great and grave objection is the unscientific spirit of the presentation, the narrowness of the base of anatomical fact upon which this far-reaching generalisation is raised. We find this disposition to what is really the old theological trick of dogmatism, again and again in his book, and it is the evident and necessary consequence of an attempt to touch the far-reaching theories of comparative anatomy without a sufficient preliminary study of individual types.

It is odd that we should find another aspect of the same mistake cropping up in one chapter of Mr. Clark's extremely useful and well-arranged handbook for the beginner in microscopy. It is in almost every way a well-arranged and well-written work, and will be particularly a boon to the amateur to whom experienced advice is inaccessible. But before proceeding to the petrographical instrument, Mr. Clark has attempted a "concise description" of polarised light, which begins—

"The elasticity of the ether in space is believed to be equal in all directions. The same is true of the ether in non-crystalline substances and in crystalline substances of the cubical system. The particles of ether are consequently free to vibrate equally in all directions. In other crystalline substances the elasticity of the ether is modified by the crystalline structure. In some crystals there is one axis or direction about which the molecules are arranged in a uniform manner; such crystals are said to be uniaxial. In other crystals there are two such axes."

Now we believe a student who will clearly understand this will be sufficiently advanced not to require it, and that to the raw beginner, this passage, and its context, will be incomprehensible. Were it not for the actual evidence of these books it would seem the most unnecessary thing in the world to assert that a clear working idea of the *theory* of polarised light, or the general ideas of chemistry and physics, or a cyclopædia of the anatomy of the metazoa, cannot be imparted in half a dozen pages or so of text. If it could, our textbooks in these subjects would be unnecessary, for the ultimate aim of all intelligent research and teaching in pure science is broader and simpler general notions, and there can be no need for a volume if a handbill will suffice. Cannot the scientific writer insist upon the proper sequence of studies in his preface, and proceed on the assumption that his counsel will be observed? To positively encourage students to proceed to subjects for which they have not the necessary grounding, to proffer them snap-shot chapters upon these neglected preliminaries, is really, we are persuaded, to place a grave impediment in their way to genuine knowledge, all the graver because it seems a help, and to place one also in the way of our advance towards more efficient science teaching in the future.

H. G. WELLS.

OUR BOOK SHELF

Climbing and Exploration in the Karakoram-Himalayas. By William Martin Conway, M.A., F.S.A., &c. Containing Scientific Reports. (London: T. Fisher Unwin, 1894.)

THIS supplementary volume contains reports on the scientific results of Mr. Conway's adventurous journey, with his map of the mountain region between Rakipushi and Golden Throne, through which he travelled. The author supplies a list of measured altitudes and notes on the map, mentioning the differences from that of the Trigonometrical Survey of India. Lieut.-Colonel A. G. Durand describes the ethnology and later history of the

Eastern Hindu Kush, giving a brief sketch of the physiography of the region. Prof. T. G. Bonney and Miss C. A. Raisin furnish notes on the rocks collected by Mr. Conway, from which it appears that the majority much resemble those of the Alps. The most interesting specimens are a peculiar schist with secondary mica, a piedmontite-schist, and a fragment allied to pseudo-jade. Mr. W. F. Kirby identifies the butterflies, Dr. A. G. Butler the moths, and Mr. W. B. Hemsley the plants. Of the last about a dozen were obtained at or over 16,000 feet. The well-known *Saxifraga oppositifolia* was gathered at 17,000 feet, and another species (the highest habitat) at 17,320 feet. Mr. W. L. H. Duckworth writes on two skulls brought from Nagyr, and Prof. C. Roy discusses Mr. Conway's notes on mountain sickness, coming to the conclusion that the primary cause of it is asphyxia. Mr. Conway's observations agree with those of other experienced climbers, that a man in good condition begins to feel the effect of increased altitude at about 16,500 feet. The fact that he is sensible of more inconvenience when in a hollow among the peaks than when on an exposed ridge, Prof. Roy attributes to some loss of oxygen by the air when it has passed over a considerable tract of melting snow. Mr. Conway has made valuable additions to our knowledge of the geography and physical history of this remote mountain region, and the present volume supplements the more popular account of his travels, which appeared earlier in the year.

The Royal Natural History. Edited by Richard Lydekker, B.A., F.R.S. Vols. i. and ii. (London: Frederick Warne and Co., 1893–94.)

ABOUT twelve months ago (NATURE, vol. xlix. p. 220), in a short notice of the two first parts of this work, we heartily recommended it as worthy of the notice of our readers. On a careful perusal of the two volumes now before us, which equal one-third of the projected series, we still feel quite justified in our recommendation; the illustrations are for the most part extremely good, and the text is not only interesting, but it is also intelligently written.

The first of these volumes treats, in fifteen chapters, of the Primates, the Chiroptera, the Insectivora, and the Carnivora, as far as the dogs. We would especially notice the chapters on the cats and the dogs, as having information well up to date. Instead of the often-quoted old stories, it is refreshing to meet with accounts of the habits of these animals, taken from the writings of V. Ball, Blandford, Guillemard, Hudson, and Sterndale. Thus, in the account of the common Indian mungoose, we find mention of the results, to within the last year or two, of Mr. Espent's experiments of introducing this little carnivore to Jamaica. The sugar-planting industry in this island was threatened with destruction on account of the swarms of rats; within three or four years after the introduction of the mungoose the rat plague came to an end, and the beneficial results to the island exceeded £150,000 a year. Volume ii. commencing with the bears, finishes the Carnivora, and describes the hoofed mammals. The illustrations play so important a part in these volumes, that we would suggest that the comparative sizes of the figures should always be given, and when possible the reader should be told where the figures first appeared.

Kitchen Boiler Explosions. By R. D. Munro. Pp. 44. (London: Charles Griffin and Co., 1895.)

THE time having again arrived when domestic boilers will be a source of trouble to paterfamilias, Mr. Munro comes forward with an account of a series of experiments with red-hot kitchen boilers, apparently reprinted from the *Transactions* of some Society. Whether this be so or not we do not wish to inquire, but to us it seems that the diagrams of steam-pressure are little suited to the "intelligent householder" for whose edification they are intended. The chief conclusions drawn from the experiments are that (1) a dead-weight safety-valve should be fitted to every boiler; (2) water will flow into a red-hot boiler although there is no free outlet, and, also, that a steam-pressure can be attained in such circumstances sufficient to cause rupture of the strongest boilers in use; (3) whilst a very high steam-pressure may be generated in a red-hot boiler by the sudden injection of cold water, a disastrous explosion cannot thus be produced; (4) an explosion, in the true sense of the word, cannot occur unless the boiler contains water as well as steam. Probably the perusal of Mr. Munro's book will help to diminish the disasters from boiler explosions.

The Island of Madeira, for the Invalid and Naturalist. By Surgeon-General C. A. Gordon, M.D., C.B. Pp. 110. (London: Baillière, Tindall, and Cox, 1894.)

PERSONS who are fortunate enough to be able to leave England during the dreary months of winter, and who select to sojourn in Madeira—"The Flower of the Ocean"—should take this brochure with them. The characteristics of the people and the place are concisely stated, and there is more information on the geology, meteorology, zoology, and botany of the island than is usually given in guide-books of a similar kind. It is well known that Madeira has an extensive fauna and flora, and we agree with the author that it is a matter of regret that the island has no public museum where they could be collected and investigated. Prof. Smitz, however, is gradually forming such an institution at the college in Funchal.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

"Acquired Characters."

Now that the correspondence on this subject, which you allowed me to start in your number of November 1, seems drawing towards a close, I ask leave through you to thank your correspondents for their courtesy in replying to my inquiries, and also to make a few observations by way, so far as I am concerned, of conclusion.

As none of your correspondents has found any fault with the conditions which I suggested as essential to a good definition, I conceive that I may assume them to be correct.

Furthermore, as none of these writers has adopted or defended any of the definitions which Weismann appeared to me to give or to suggest, or has said anything by way of criticism on my strictures on these definitions, I think that I may conclude that I was not far wrong in those strictures, and that Weismann's writings do not afford any good definition of the words to which he has given currency.

Mr. Poulton has suggested that a definition may be found in the statement that "whenever an organism reacts under an external force, that part of the reaction which is directly due to the force is an acquired character." But surely this is difficult of application: for in every case of a reaction on an external stimulus there are two elements—viz. first, the internal capacity to respond, and secondly, the external force or stimulus. Each of these is necessary to the result and to every part of the result, and neither is of itself sufficient to the result or to any part of the result. How then can we analyse or break up the result or the reaction into two parts, and say that the one is the direct result of the external force, and the other is either not its result at all, or its indirect result? Where there is the joint action of two causes, each necessary but neither sufficient of itself, I conceive that you cannot either logically or physically sever any part of the result from the action of both of the causes, and there is no ground for attributing directness to one part of the the effect, and indirectness to another. Mr. Poulton dwells truly on the reaction having two causes—the internal and the external; but this does not justify the analysis of their results into two parts.

Nor does the matter become plainer to me when I follow Mr. Poulton in his application of his definition to concrete cases. The first is the case of the so-called "Exercierknochen," a reaction on an external force resulting in a certain number of changes of tissue. How is it possible to classify those changes into two categories—the one including changes directly due to the external force, the other changes not directly due to it? If the stress is to be laid on the word "direct," then one must respectfully ask what is its meaning? how is it to be ascertained and verified? one must inquire whether what is said to be an indirect result, means anything but a result which is transmitted? in which case we should find ourselves in a vicious circle. I will not follow Mr. Poulton through the other instances, but I believe the reader will find, like me, that each raises similar difficulties, and that in no case does he analyse the actual result into two distinct and separable parts.

Mr. Galton proposes, and Prof. Ray Lankester adopts another definition, viz. "Characters are said to be acquired when they are regularly found in those individuals only who have been subjected to certain special and abnormal conditions." Now I suppose that characters can be found regularly only either (1) in individuals exposed to conditions which induce them, or (2) in individuals who have inherited them. To say, then, of a character that it appears only regularly in individuals exposed to certain conditions, is to say that it does not appear in individuals by inheritance, and the proposition that acquired characters are not transmissible is thus reduced to an identical one. The possibility of inheritance is excluded by the definition, and the inquiry whether acquired characters are inherited is impossible.

I do not propose to follow your learned correspondents into many of the subjects touched on by them; but the more their letters are read, the more apparent does it become that they are not at one, either with themselves or with Lamarck or Weismann, as to the use of the words "acquired characters;" and for myself, I repeat my regret that an inquiry of great moment should be obscured, as I venture to think, by a premature use of classificatory words before the real classification of nature herself has been ascertained. For the question, "Are acquired characters transmissible?" I hope to see substituted the inquiry "What characters are transmitted?"

EDW. FRY.

The alleged Absoluteness of Motions of Rotation.

All motion is relative. This apparently universal statement is a particular statement about the meanings of words. The word "motion" means "relative motion," or, more precisely, "the motion of a body" means its motion relative to other bodies. We may go further and make the still more fundamental statement that *all position is relative*, or, in other words, the position of a body means its position relative to other bodies. It is easy for anyone who puts words together without reflecting sufficiently on their meaning to put together the noun "motion" or "position" and the adjective "absolute," but the expressions "absolute motion" and "absolute position" are nevertheless meaningless, just as much so as "white blackness," "retrograde progress," "the action between a rough body and a smooth body at their point of contact," or "the potential energy of non-conservative forces."

The above remarks contain the standpoint from which it is concluded that motions of rotation are no more "absolute" than motions of translation. Anyone who accepts them for translation, but rejects them for rotation, places himself in an illogical position. Unless I have misunderstood them, this is the position occupied by Maxwell and Prof. Greenhill. The standpoint of those who assert that position and motion are in all cases relative is directly opposed to that of Newton. He held that there is absolute position in immovable space, and relative position with respect to bodies, and correspondingly there are absolute and relative motions; that absolute motion of a body is its transference from one absolute place to another absolute place; that we can never determine the absolute place of a body, but only its relative place; that in cases of rotation we can distinguish absolute from relative motion by the effects of "centrifugal force." He gives no indication how to distinguish absolute and relative motions of translation. From the impossibility of determining the absolute position of a body it seems to follow that absolute motion of translation cannot be determined; this view is adopted by Maxwell.

Assuming that it is the object of the Science of Mechanics to give as simple a description as possible of the observed facts about the motions of bodies, the assumption at the outset of absolute motions or positions about which we can know nothing appears an unnecessary complication.

From a logical point of view the cardinal statement in the discussion is that all position is relative. It appears to be conceded by Newton, and has been insisted upon by Maxwell, that all knowable position is relative. To say that at any instant a body has an absolute position in space, but that we can never know where it is except by reference to other bodies, that is to say that every body has an absolute position, although we can only know its relative position, is to introduce an unnecessary complication, if it is not to talk nonsense.

What is done in practice is to determine the position of a point by reference to a Cartesian system of axes, or by an equivalent method. What is called "the velocity of a body" is its velocity relative to the axes; what is called "the acceleration of a body" is its acceleration relative to the axes; a body has a motion of rotation when the angles between lines of the body and any axis are changing with the time. It is part of the solution of a mechanical problem, as presented by any set of observed facts, to determine the system of axes with reference to which the description of the observed motion becomes as simple as possible, and there exists a calculus for transforming the expression of a motion from one system of axes to another when the relative motion of the two systems is known.

The question how the axes are to be determined has been much discussed, but no general answer appears possible. Particular answers apply in particular cases. In general any three points, not in a straight line, determine a set of coordinate axes. For one of the points may be chosen as origin, the line joining this point to another of the points may be chosen as one coordinate axis, and the plane of the three points may be chosen as one coordinate plane. For the three points any identifiable parts of bodies may be taken; but, in general, axes so chosen will be inconvenient, or, what comes to the same thing, the description of a motion by reference to them will not be simple.

The description of motion is generally made in terms of the concept *force*, that is to say, we state the acceleration relative to the axes which a free body placed in a given position relative to the axes, and moving with a given velocity relative to the axes would have, and the nature of the constraints which give rise to differences of acceleration in a constrained and a free body moving through the same position with the same velocity relative to the axes. In an actual problem the acceleration of a free body whose other circumstances (position and velocity relative to the axes) are known, must be found by experiment. It does not concern the matter now under discussion that among these circumstances position is generally predominant over velocity in determining accelerations. What is of more importance is the fact that *the force acting on a body depends on the system of axes chosen.* For the force is a vector quantity whose line of action coincides with the line of the acceleration relative to the axes, and whose magnitude is proportional to this acceleration. This point has been noted by Maxwell. The result that the field of force depends partly on the axes is frequently a guide to the choice of convenient axes of reference, namely, we choose axes with respect to which the expression of the field of force is simple, and it often happens that in this way all motional forces, other than frictional resistances, can be made to disappear. An easy and striking example of the differences introduced by changing the axes can be found by considering the motion of two particles which move in one of the planes chosen as coordinate planes with uniform velocities in different lines relative to the coordinate axes. If a new set of axes is constructed by taking one of the particles as origin, and the line joining the particles as one axis, the acceleration of the other particle relative to the new axes is directed towards the first particle, and varies inversely as the cube of the distance between the two particles. Another very interesting example is furnished by Foucault's pendulum, to be discussed presently.

These remarks will serve as a preparation for the way in which we interpret, in accordance with the principle of the relativity of motion, those experiences which have been held to favour the view that motions of rotation admit of absolute determination. The history of the discussion appears to show that little would have been heard of this doctrine apart from the desire to explain to a public unused to regard motion as relative the theory of the rotation of the earth. To one who has mastered the relativity of motion it is manifestly the same thing to say (1) that referred to axes fixed in the earth all the stars describe circles every day about the polar axis, or (2) that referred to axes fixed among the stars the earth rotates about its polar axis once a day. If any ground can be alleged for holding that one of these statements is the simpler, that is a ground for a certain choice of axes, not for saying that one motion is "real" or "absolute," and the other "relative" or "apparent."

All the so-called "proofs of the earth's rotation" are deductions from particular experiences which show that other motions besides the diurnal relative motions of the earth and stars are more simply expressed by referring to axes fixed among the stars than by referring to axes fixed in the earth. They all depend on the specification of "the acceleration due to gravity" near the earth's surface. The neighbourhood of the earth is a field of force, and the magnitude and direction of the force at any point depend on the axes of reference. The specification of the field of force is simplest when referred to the centre of the earth as origin, and to axes fixed in direction with reference to the stars. The field is then expressed by the law of gravitation.

It is worth while to elucidate this matter in greater detail by an examination of the most famous of these "proofs," that by means of Foucault's pendulum. What is observed is that if the pendulum is really free to swing about a point, and if the bob always passes above the same point of a horizontal table (fixed with reference to the earth) when at the lowest point of its swing, then the plane of vibration turns slowly round, so that the line of vibration is above now one, now another line drawn on the table, the oscillation in the line being practically simple harmonic. If this motion were referred to axes fixed with reference to the table, there would be a component acceleration from the bob of the pendulum towards the point of support (to be accounted for by the constraint), a component acceleration in the plane of vibration at right angles to the former (which we should recognise as a component of gravity), and a component acceleration perpendicular to the plane of vibration, and proportional at any instant to the velocity in the simple harmonic motion. If we had nothing else to guide us, no observation of the stars, no theory of gravitation, but knew only from less refined observations that free bodies fall downwards with constant acceleration, we should have to do two things: we should have to try to simplify the specification of the acceleration of the bob of the pendulum by referring to a new set of axes, and we should have to conclude that our previous observations of falling bodies had not disclosed all the facts about the field of force in the neighbourhood of the earth. We should simplify the specification of the observed accelerations by referring to axes which (relative to the earth) rotate with the plane of vibration of the pendulum, and we should conclude that such axes are required in order that the laws governing the motion of falling bodies may be correctly formulated. What the experiment with Foucault's pendulum really proves is not that the rotation of the earth relative to the stars is an "absolute motion," but that the system of axes, with reference to which the acceleration of a free body near the earth's surface is of constant amount and directed towards the earth's centre, is not fixed in the earth, but (relative to axes fixed in the earth) these axes rotate with the stars.

It will be found on examination that every other so-called "proof of the earth's rotation" is of the same character. By each it is shown that the earth rotates in the same time and in the same way relative to the axes required for the statement of the law of gravitation as relative to the stars. It is not legitimate to suppose that two relatives make one absolute.

It is true that the conclusion at which we have arrived takes longer to state, and appears at first sight less simple than the statement by way of "absolute motion," but it contains no undefined terms, and no reference to anything assumed to exist, but about which nothing can be known.

Objection has been taken to the attempt to express mechanical theory in terms of relative motion, on the ground that it will be perplexing to beginners, and difficult at any stage. In answer to this it may be urged that in teaching beginners there is no need to say anything about either relativity or absoluteness. The motions that interest them are motions relative to the earth; the motions of boats, trains, cricket-balls, billiard-balls, and machinery; things that can be sufficiently described by reference to lines fixed in the earth. It is only at a later stage when general mechanical theories have to be studied, and a foundation laid for physical astronomy and mathematical physics, that is proper to insist on the relativity of motion; and at this stage it appears to me more important that our statements of principles should be free from metaphysical obscurity than that they should be verbally short.

A. E. H. LOVE.

The Antiquity of the "Finger-Print" Method.

SIR WILLIAM HERSCHEL, in his letter to NATURE (Nov. 22, p. 77), expresses his unbelief in the statement in the *Nineteenth Century* (No. 211, p. 365), which ascribes to the Chinese the original invention of the "finger-print" method of personal identification. While I do not know upon what Mr. Spearman has founded this statement, I have collected from a few sources some facts which seem to justify the claim made on behalf of the Chinese.

Although at present I have no record to refer to, it is a fact that every Japanese, old enough to have outlived the *ancien régime* that passed away in 1869, well remembers the then current usage of "stamping with the thumb" (*Bo-in*) on legal papers, popularly called "nail-stamp" (*Tsume-in*), on account of the common use of a thumb with the edge of its nail in ink; whereas on papers of solemn contract, accompanied by written oath, the "blood-stamp" (*Keppan*), or the stamp of the ring-finger in blood drawn therefrom, was demanded.[1]

Chûryô Katsurakawa, the Japanese antiquary (1754–1808), writes on the subject as follows: "According to the 'Domestic Law') (*Korei*), to divorce the wife the husband must give her a document stating which of the Seven Reasons[2] was assigned for the action. . . . All [letters] must be in the husband's handwriting, but in case he does not understand how to write, he should sign with a finger-print. An ancient commentary on this passage is: 'In case a husband cannot write, let him hire another man to write the document . . . and after the husband's name sign with his own index-finger.' Perhaps this is the first mention [in Japanese literature] of the 'finger-print' method" (1) This "Domestic Law" forms a part of the "Laws of Taihô" enacted in 702 A.D.; with some exceptions, the main points of these "Laws" were borrowed and transplanted from the Chinese "Laws of Yung-Hwui" (*circa* 650–55 A.D.) (2); so it appears that the Chinese of the 7th century A.D. had already acquired the "finger-print" method.

After the above-quoted passage, Katsurakawa continues thus: "That the Chinese apply on divorce-papers the stamps of the ends of the thumb and four fingers, which they call 'Shau-mú-ying' (*i.e.* hand-pattern stamp) is mentioned in 'Shwui-hü-chuèn,' &c." (3). This "Shwui-hü-chuèn" is one of the most popular novels enjoyed by the modern Chinese—so popular that I have met with many Chinese labourers possessing it in the West Indies; its heroes flourished about 1160, and its author lived in the twelfth or thirteenth century A.D. (4). As is usual with many other examples, this novel gives us more accurate descriptions of minor institutional features that co-existed with either the heroes or the author, or both (5). After making careful search in this novel, I can now affirm that the Chinese in the twelfth or thirteenth century used the finger-prints, not only in divorce, but also in criminal cases. Thus the chapter narrating Lin Chung's divorce of his wife, has this passage: "Then Lin Chung, after his amanuensis had copied what he dictated, marked his sign-character, and stamped his 'hand-pattern'" (6). And in another place, giving details of Wu Sung's capture of the two women, the murderers of his brother, we read: "He called forth the two women; compelled them both to ink and stamp their fingers; then called forth the neighbours; made them write down the names and stamp [with fingers]" (7).

It has been lately suggested by my friend, Mr. Teitarô Nakamura, that possibly the "finger-stamp" was merely a simplified form of the "hand-stamp," which latter method had once been so current in Japan that it gave to the documents the common names "Tegata" (*i.e.* hand-pattern) and "Oshite" (*i.e.* impressed hand)[3] (8). This view applies equally well to

[1] The "thumb-stamp" was equally regarded with the formal engraved seal (*Jitsu-in*), but the "blood-stamp" had nothing to do for identification. For the formula of the latter mode of stamp, *vide* Ota, "Ichiwa Ichigen," new edition, Tokyo, 1882, vol. xiii. p. 39.

[2] The Seven Reasons for divorcing the wife are: (1) filial disobedience; (2) barrenness; (3) licentiousness; (4) jealousy; (5) leprosy; (6) loquacity; (7) larceny.

[3] It must not be presumed as a fact that after the "finger-stamp" was introduced, it soon supplanted the "hand-stamp"; for even in the seventeenth century the latter was sometimes used, as is instanced in the writing of Katô-Kiyomasa (1562–1611) preserved in a monastery near Tokyo. *Cf.* Kitamura, "Kiyû Shôran," new edition, 1882, vol. iv. p. 16.

the case of the Chinese, for they still use the name "hand-pattern" for the finger-print (see above). That this "hand-stamp" was in use in an ancient kingdom of Southern India, there is a proof in the Chinese records (9).

When we recognize that the hand-marks were early in use for identification by the three distinct nations, the Japanese, Chinese, and Indians, and when we consider that even the teeth-marks were so commonly used for authentication in India that the heir-apparent to As'ôka Râdja did not hesitate in plucking out his own eyes on recognizing the king's teeth-mark that accompanied the false epistle (10), it would seem quite true that among those ancient nations who were, with few exceptions, ignorant of the use of "written signature" method, it was but a natural process that the methods were invented to apply to identification some more or less unchanging members of human body.

Further, that the Chinese have paid minute attention to the finger furrows, is well attested by the classified illustrations given of them in the household "Tá-tsáh-tsú"—the "Great Miscellany" of magic and divination—with the end of foretelling the predestined and hence *unchanging* fortunes (11); and as the art of chiromancy is alluded to in a political essay written in the third century B.C. (12), we have reason to suppose that the Chinese in such early times had already *conceived*—if not perceived—the "for ever unchanging" furrows on the finger-tips.

KUMAGUSU MINAKATA.

15 Blithfield Street, Kensington, W., December 18.

Peculiarities of Psychical Research.

MAY I enter an emphatic protest against the notion insinuated both by Mr. Wells and Prof. Karl Pearson, that "Psychical Researchers" are a sort of sect engaged in spiritualistic or other propaganda? Most people, I am afraid, fight shy of psychical research, either because they are afraid that *if* there is anything in it it is the devil, or because they have a scientific reputation which they are afraid of losing. I do not know to which category Mr. Wells belongs, but apparently he fails to understand that in order to make out a case against psychical research he has got to show, not that the existence of telepathy and clairvoyance has not been proved, but that there is not even a *prima facie* case worth investigating. When we remember that ten years ago "mesmerism 'was included along with telepathy and clairvoyance, we shall not attach much importance to such efforts to stifle inquiry. Even if the result should be to confirm Mr. Wells's anticipation, and show that all the coincidences that have been reported can be explained away as mistakes or misstatements, the inquiry will yet have been worth the labour bestowed on it, if only as affording a measure of the value of testimony to the miraculous. And if this comes to pass, the bigots of science will be ready enough to claim a share in the work, if only by saying, "I told you so!"

I do not know what Prof. Karl Pearson means by his quite gratuitous attack on "the scientific acumen of the psychical researchers." Surely he cannot imagine that they overlooked the point which he has unearthed? The instructions to the experimenters were, that "the agent should draw a card at random, and cut the pack between each draw" ("Phantasms of the Living," vol. i. p. 33, foot-note). Could an abnormal distribution of the cards affect the result if those precautions were taken, or has the Professor any reason to suppose the instructions were not carried out? EDWARD T. DIXON.

Cambridge, December 14.

THE following are a few of my grounds for questioning the scientific acumen of the psychical researchers:—(1) M. Richet's experiments are cited as if they were significant of telepathic action. On the contrary, they give odds of so little weight that they are significant of nothing but want of acumen. I have in card drawing, tossing and lottery experiments, all conducted with every precaution to secure a random distribution, obtained results against which the odds were more considerable. (2) Mr. Dixon is unable to see the importance of ascertaining whether there was an abnormal distribution in the cards cut or the cards guessed. His inability is a strong confirmation of my standpoint. (3) I have heard lectures, and read papers written by psychical researchers. Both alike seem to me akin to those products of circle squarers and paradoxers, with which, as a reviewer, I am painfully familiar. As a concrete example, I take my friend Dr. Oliver Lodge's psychical papers. They are typical, to my mind, of the manner in which the scientific acumen of even a professed and most highly competent man of science vanishes when he enters this field of "research."

I do not intend to take part in a controversy on the subject at the present time, but I do suggest that no better exercise could be found for a strictly logical mind with plenty of leisure than a criticism of the products of the chief psychical researchers. Such a criticism would be of much social value, in the light of recent attempts to popularise the "results" reached by these investigators. KARL PEARSON.

University College, London, W.C. December 19.

The Artificial Spectrum Top.

I HAVE read with interest Prof. Liveing's theory of my artificial spectrum top as summarised in NATURE of Dec. 13, p. 167, and am sorry I did not know of his conclusions before he made them public, because a very simple experiment would, I think, have convinced him of their inaccuracy. If Prof. Liveing, or any of your readers, will examine my top rotated in the light of a *bright* sodium flame, they will find that the colours are quite distinct. I know of no other way of seeing blue and red by the light of sodium, and the phenomenon, I think, shows decisively that the colours of the top are "artificial" sensations in the sense explained in my theory of the instrument.

December 16. CHARLES E. BENHAM.

I HAVE examined Mr. Benham's top by the light of a bright sodium flame, but have failed to see anything like the colours which I see by daylight or by the light of an incandescent electric lamp. By the sodium light the outmost three circles appear, when the rotation is one way, to be dark brown, the inmost three dark leaden grey, while the intermediate circles are paler brown. Reversing the direction of rotation interchanges the appearances of the outmost and inmost three circles. I cannot see any red or blue, or green, in any case. Other people here seem to see much the same as I do when the top is illuminated by the sodium flame only. With certain black and white figures of my own, I can get a pink appearance in the sodium light, but no green or blue. With spiral figures, which are worrying to look at, I find that some people can see a play of colour even with the sodium light, but I do not see it myself. Using a turn-table, by which the rate of rotation can be regulated at will, I have found that the speed, in white light, required to bring out the colours is decidedly different for different people. This fact convinced me that the explanation of these very curious appearances must be looked for in some physiological cause. It is perhaps worth remark that a sodium flame, when there is much sodium in it to make it bright, is by no means monochromatic, though sufficiently so to make the experiment with the top a very interesting one; and as Mr. Benham sees colours by this light which some others fail to see, it goes far to prove the phenomenon to be subjective.

Cambridge, December 19. G. D. LIVEING.

"Solute."

CORRESPONDING to the words "solvent" and "solution," some word is very badly wanted to express "the dissolved substance." The analogous word is evidently "solute," and it is as short and euphonious as the others. May I inquire why it is not in general use? Surely some one must have proposed it?

Leipzig. F. G. DONNAN.

"The Elements of Quaternions."

IN answer to my reviewer's question (*vide* p. 154), I must frankly admit that

(*a*) Eq. 8, p. 40, should have been a group of six equations, $i = \sqrt{-1}, j = \sqrt{-1}$, &c.; and that

(*b*) The inference should have been that i, j, &c., are (unequal) square roots of negative unity.

H. W. L. HIME.

THE LICK OBSERVATORY.

THE recent issue of volumes ii. and iii. of the "Publications" of the Lick Observatory serves to give some indication of the growing activity of this world-famed institution, and to foreshadow the great part which it is destined to play in the astronomy of the future. As in the case of so many other observatory publications, these volumes contain much with which the various astronomical journals have already made us familiar, and one of their chief objects appears to be to collect the observations into a convenient form for reference.

Volume ii. is entirely devoted to the magnificent micrometric work on stars and nebulæ performed by Mr. Burnham during his four years' connection with the Observatory, which, to the general regret, terminated in June 1892. It will be a matter of satisfaction to all interested in the progress of astronomy to learn that this keen-sighted astronomer has nothing but praise for the great telescope. He says: "It has more than satisfied the severest tests which could be applied, and the highest expectations concerning its performance have been realised. It is a monument of the genius and skill of the unrivalled opticians, Alvan Clark and Sons, to whom the progress of astronomical work all over the world is so largely indebted." The fact that powers up to 2600 have been successfully employed, further emphasises the excellence of the objective.

Mr. Burnham strongly insists upon the advantages to be gained by the use of a micrometer in which the wires are bright on a dark field. With this method of illumination, he tells us, "any object that can be seen under any circumstances, however faint, can be well and accurately measured. There is no such thing as a star too faint for measurement, if it can be seen at all."

Besides the immense number of numerical results, the volume gives a mass of most interesting information relating to the various objects observed. Some of this has already been published, but many new points have been added. Thus, it appears that the observations of θ Orionis show that "the six principal stars are absolutely fixed with reference to each other, so far as any change is concerned which could be detected by observations covering more than half a century." The fulness of the account of this remarkable group, and of the numerous supposed discoveries of stars within the trapezium, furnish an excellent example of the thoroughness which is so characteristic of Mr. Burnham's work. With reference to the very faint star discovered within the trapezium by Mr. Alvan E. Clark soon after the telescope was erected, he writes: "It is a difficult object with the 36-inch, and certainly has never been seen before, notwithstanding the numerous alleged discoveries with telescopes down to three or four inches aperture. Not less than a dozen of these imaginary stars have been distributed about the interior of the trapezium."

To the average astronomer, the star 95 Ceti would probably not be of absorbing interest, but to Mr. Burnham it is "the most mysterious and strange double star in the heavens." The companion was discovered by Clark with a $7\frac{1}{2}$-inch, was subsequently measured by Dawes in 1854, and by Burnham with some difficulty in 1888, since when he has not been able to see it even with the 36-inch.

Mr. Burnham finds that "none of the stars which have been supposed from spectroscopic observations to be close doubles, have shown any evidence of the fact when examined with the large telescope under the most favourable conditions." He then goes on to say that "it is possible some other explanation will be found for the recurrent phenomenon first discovered by Miss Maury in the Harvard spectrum photographs. At all events, it is hardly worth while, until the method has been verified upon some of the numerous known pairs suitable for this purpose, to consume the valuable time of the great telescope in a further examination of objects of this class." One would almost imagine that Mr. Burnham had failed to grasp the fact that the separation of the component stars in such cases, by the spectroscopic method, is solely due to their relative velocity, which in ordinary pairs is relatively small. At any rate, it has been estimated that a telescope of sufficient dividing power to separate the components of β Aurigæ must have an aperture, not of three, but of eighty feet!

Limitations of space forbid further reference to the rich feast which Mr. Burnham has provided; the value of much of his work will probably be only fully realised by astronomers of another age, but at the same time a large proportion of his results are of the greatest immediate interest and value.

Vol. iii. of the "Publications" consists of Prof. Weinek's now well-known selenographical studies; a report on specimens of glass similar to those used in the construction of the great object-glass; an investigation of the glass scale of the measuring engine; and Prof. Keeler's observations of the spectra of nebulæ.

It comes as a surprise to us to learn from Prof. Holden's introduction to this volume, that the work of the Lick Observatory is not without danger of suffering for want of funds. Even so small a matter as a suitable instantaneous shutter "could not be constructed until the summer of 1893, for lack of funds and of skilled workmen." In the early stages of the lunar photographic studies, we are also informed that the work would have been seriously interrupted had not the Smithsonian Institution come to the rescue with "several small appropriations of money." The appearance of the present volume has been made possible by the generosity of Mr. Walter W. Law, of New York City, in providing funds to cover the whole cost of producing the fifteen magnificent plates of the moon which embellish its pages. They are modestly described as "a gift to science," and they afford another example of the practical sympathy with astronomical inquiries displayed by so many of our American cousins.

Few will be inclined to deny the great value of the lunar photographs which have been taken at the Lick Observatory, and it is a matter for congratulation that the astronomical world has so soon been made acquainted with the first-fruits of their investigation.

Prof. Holden tells us that it was quite impossible to undertake the investigation of the negatives at the Lick Observatory, owing to the limited staff, and they were therefore placed freely at the disposal of Prof. Weinek, "whose previous experience in lunar observations and in photography, as well as his very unusual artistic skill, made his advice and assistance of extreme value."

No pains have been spared to make the study of the objects selected as complete as possible. As an instance we may mention that Prof. Weinek's drawing of Copernicus, enlarged twenty times from the negative, represents the great labour of $224\frac{3}{4}$ hours, and is described by Prof. Holden as "a monument of skill and patience."

It is proposed that a complete map of the moon, on a scale of 3 feet to the diameter, shall eventually be made, though the practicability of making a map on four times the scale is demonstrated by an enlargement of Tycho. The photograph of the Lunar Apennines, on the 3-foot scale, reproduced in Fig. 1, is a magnificent example of a camera enlargement from one of the negatives.

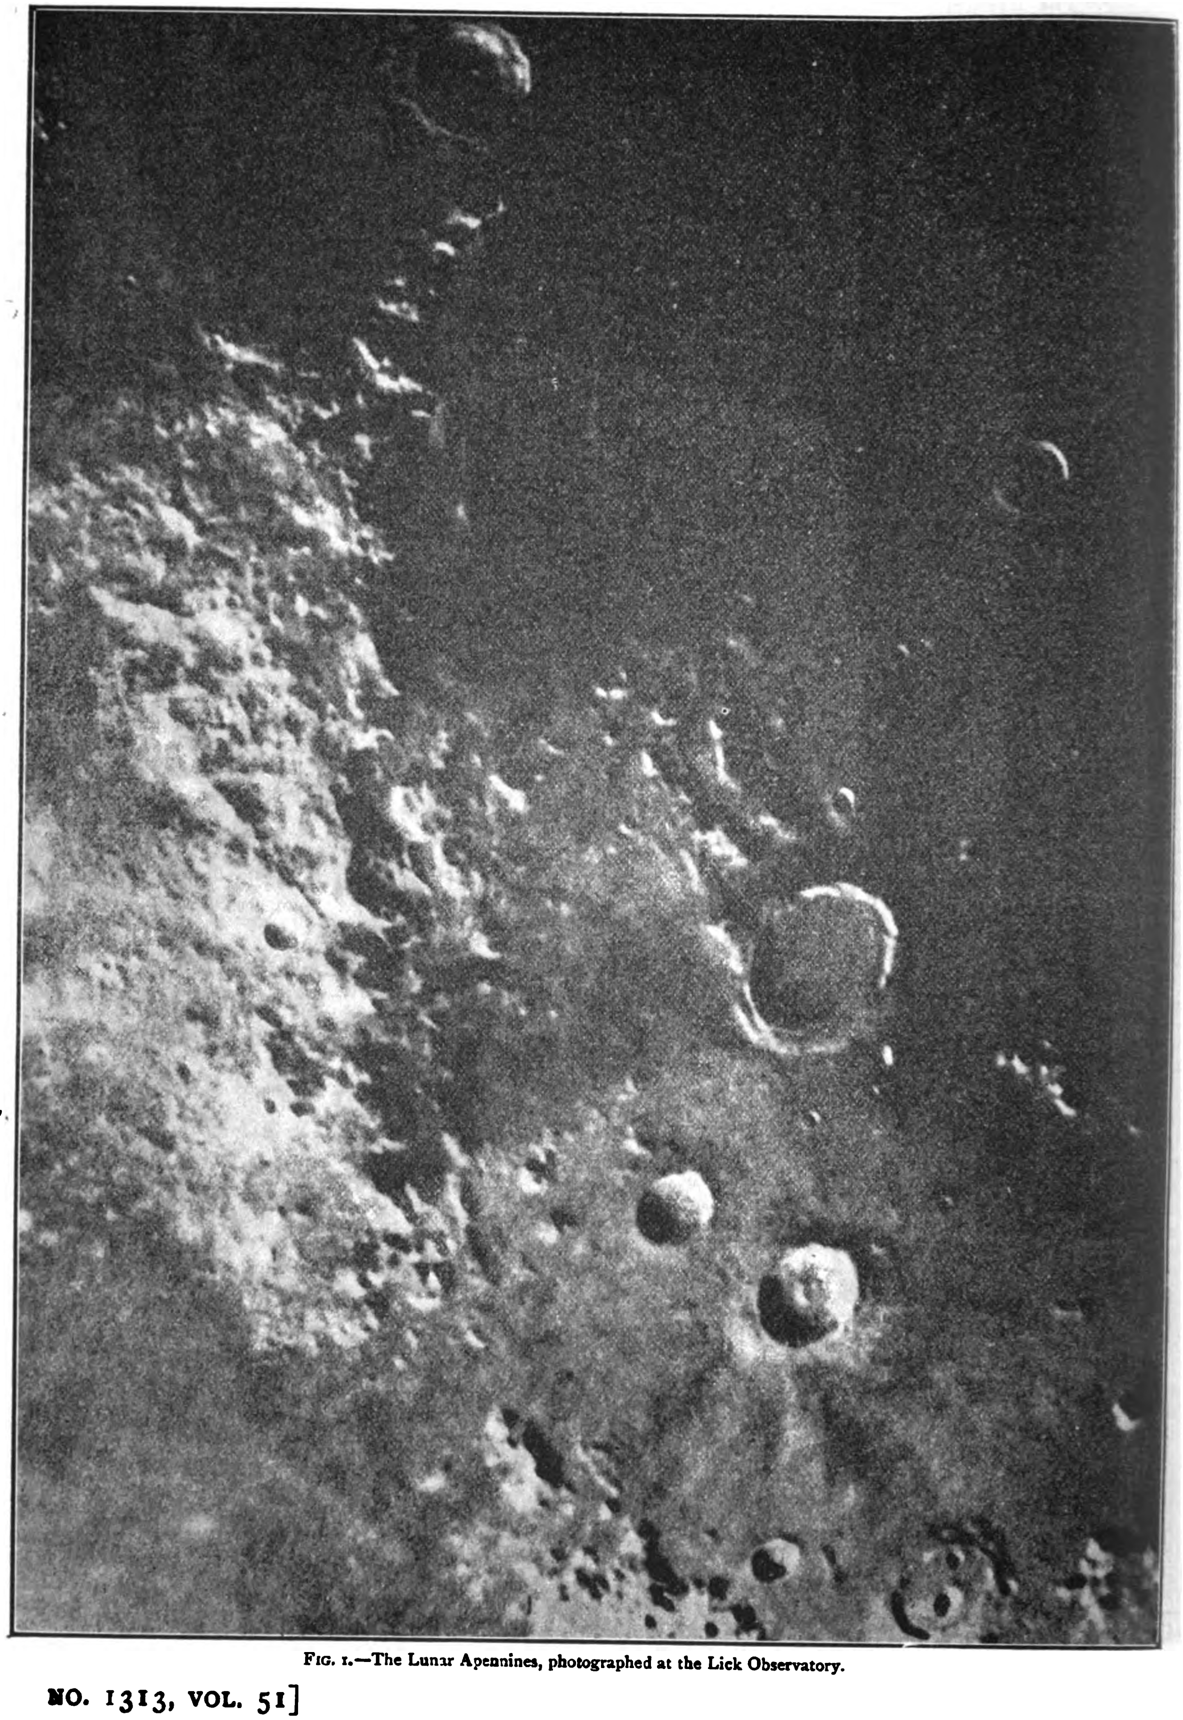

Fig. 1.—The Lunar Apennines, photographed at the Lick Observatory.

Several points of great interest are touched upon by Prof. Holden, among which is a brief discussion of the dimensions of the smallest object on the moon which can be registered on the photographic plate by the 3-foot refractor. From this we learn that a crater on the moon which is less than one-tenth of a mile in diameter will form an image which is about the same size as the grains of silver in the photographic film, and cannot in general be distinguished. Craters not more than 0·3 and 0·15 English miles in diameter, however, have been detected already. Prof. Holden concludes that for further advances in lunar photography it will be necessary to employ plates of greater sensitiveness so as to shorten exposure, and also plates in which the grain is finer. Workers in all departments of celestial photography have felt the need of such improvements, and, as Prof. Holden remarks, "future improvements depend more upon the manufacturer of plates than upon the astronomer who uses them."

Prof. Weinek's concise descriptions of the lunar formations figured in the volume, and his account of the new features so far discovered, leave nothing to be desired. Observers of the lunar surface may take consolation in the fact that even yet they are not in danger of being entirely superseded by photographic methods, for, as Prof. Weinek points out, "both methods must be perfected, and each must support the other." It is worth remark here, however, that enlargements recently made of lunar photographs taken at the Paris Observatory seem to mark a clear step towards perfection. (See page 207.)

Prof. Keeler's work on the spectra of nebulæ during his connection with the Lick Observatory, may fairly be said to mark the commencement of a new era in the history of the spectroscope as an instrument of precision. The observations were undertaken in the first instance at the suggestion of Dr. Huggins, who appealed to the Lick astronomers in 1890 in connection with the discussion as to the origin of the chief nebular line. It was found possible to use the third and fourth order spectra of a grating spectroscope with advantage, and even then the spectra were "by no means extremely feeble." Former work left the wave-lengths of the nebular lines uncertain to at least two tenth-metres, but the uncertainties now amount to only a small fraction of a tenth-metre. Further, it is claimed that the observations of the nebulæ have shown the existence of errors in Ångström's scale and in the wave-lengths of the reference lines, so that the observations did not become consistent until more reliable reference wave-lengths were determined by Prof. Rowland. As an example of the accuracy attainable, the velocity of Venus in the line of sight was found to be 6·4 miles per second at a time when the computed velocity was 7·69 miles.

It is not a part of our present purpose to discuss the origin of the chief line in the spectrum of the nebulæ, but we may say that Prof. Keeler does not favour the suggestion that it is due to magnesium; but, on the other hand, his measures definitely decide against the nitrogen origin of the line.

After all corrections have been applied, the normal positions of the first and second lines in the nebular spectrum are stated to be 5007·05 ± 0·03 and 4959·02 ± 0·04 respectively, and neither of the lines is represented among the Fraunhofer lines which appear in Rowland's photographic map. Indeed, we are not aware that either of these lines has ever been recorded as an absorption line in the spectrum of any celestial body whatever.

The observations have not been entirely limited to the determination of the position of the chief line. It has been found, for instance, that "the nebulæ are moving in space with velocities of the same order as those of the stars. Of the nebulæ observed, that having the greatest motion of approach, 40·2 miles per second, is G.C. 4373; that having the greatest motion of recession, 30·1 miles per second, is N.G.C. 6790. Most of the nebulæ have considerably smaller velocities than these."

It might well be imagined by anyone who has seen a photograph of the Orion nebula that the different parts would have a relative movement with regard to each other. Such, however, does not appear to be the case, according to Mr. Keeler; or, at least, there is no relative movement greater than four or five miles per second. Attempts to measure the velocity of rotation of the large planetary nebula G.C. 2102 showed that there was no radial motion greater than eight miles per second.

A study of the spectra of the nuclei of the planetary nebulæ has led Prof. Keeler, as it has independently led Prof. Pickering, to the conclusion that they are very closely connected with the bright-line stars, and thus the latest and most precise work goes to confirm one of the fundamental points of Mr. Lockyer's meteoritic hypothesis.

With reference to the discordant accounts of the spectrum of G.C. 826, to which attention was drawn by myself in 1889 (NATURE, vol. xli. p. 163), it is stated that Dr. Huggins's observation of a continuous spectrum in 1864 "was evidently a mistake," the spectrum being of the usual bright-line type.

Apparently in order to reconcile the presence of a continuous spectrum in such a nebula as that of Orion with the idea that masses of rarefied gas were alone in question, it has been suggested that this continuous spectrum may really be a large number of adjacent bright lines. The enormous dispersion employed by Prof. Keeler, however, fails to resolve it into lines, and thus Prof. Tait's suggestion as to the meteoritic constitution of nebulæ still stands as the best explanation of the spectrum.

Many other points of interest are raised by Prof. Keeler's admirable work, but sufficient has been said to indicate the progress which has been made in this branch of celestial physics and chemistry. Although Prof. Keeler has now removed to the Allegheny Observatory, his successor at the Lick Observatory—Prof. Campbell—has already shown himself to be fully capable of maintaining the spectroscopic department of the Observatory at the same high standard of efficiency.

A. FOWLER.

STUDIES OF A GROWING ATOLL.

THE researches of the surveying ships of the British Navy have from time to time rendered services to science no less important than those which it is their function to perform for navigation. It has become an established practice to encourage the surgeons of these vessels to undertake scientific investigations in the leisure which their professional duties frequently afford, and facilities are sometimes given for a competent man to continue such work by allowing his transference to another vessel when his own has to leave the place where he has been working. For this the Admiralty deserves credit and the thanks of those who desire to see her Majesty's ships maintaining the position they took up in the days of Cook, and continued through the voyage of the *Beagle*, and the long line of expeditions which followed it, to the voyage of the *Challenger*. While it may not be too much to hope for a renewal of special marine research by the Royal Navy before private enterprise reaps the waiting scientific harvest of the unknown Antarctic, we feel that too much prominence cannot be given to the good work done incidentally in the course of routine surveys.

The hydrographer, Captain Wharton, in his preface to the reports of Mr. Bassett-Smith on the Macclesfield

Bank,[1] expresses the general result of this piece of research very clearly and concisely, showing that its value is fully recognised by the authorities at the Admiralty.

The Macclesfield Bank is a shallow patch, rising abruptly from deep water in the middle of the China Sea, crossed by the parallel of 16° N. and frequently passed by vessels. It is of an oval shape, about 80 miles long and 30 wide, with a general depth of about 40 fathoms. Reports having been made of very shallow water on the edge of this bank, forming a possible danger to shipping, a complete survey was resolved upon, and as preliminary soundings had shown indications of a raised rim, instructions were given to pay special attention to the animal life upon what might turn out to be an atoll entirely beneath the surface of the sea. Half of the reef was surveyed by Captain Moore in the *Penguin* in 1892, and collections made by means of dredges and divers, under the superintendence of Mr. Bassett-Smith, several tons of specimens being subsequently despatched to the Natural History Museum for full study. The remainder of the bank was examined in 1893 by Captain Field in the *Egeria*, to which ship Mr. Bassett-Smith had exchanged in order to continue his work, and the result is such an investigation into the biological conditions of a submerged coral reef in mid-ocean as has never been made before.

The whole circumference of the bank rises as a ring of coral to within from 9 to 15 fathoms of the surface, being broken here and there by wide gaps of greater depth, but never so deep as the central depression, which varied generally from 40 to 48 fathoms. The minimum depth on the rim was 6½ fathoms, and an isolated shoal rising from the centre of the inner depression reached to within 5 fathoms of the surface.

The uniformity of the depth appears to Captain Wharton to be a strong argument against any movement of the bottom since the period when the atoll form was assumed; and he shows that the simple growth of coral on the rim will in time suffice to produce a perfect ring-shaped coral island without the aid of subsidence or upheaval. It appears, in fact, that here is an atoll in course of formation on a foundation sufficiently near the surface to allow coral to grow. Such a foundation Darwin admitted might allow a coral island to form without subsidence, and the recently discovered abundance of similar elevations in the tropical oceans is one of the main arguments for Murray's general theory of coral growth.

Mr. Bassett-Smith's first day's dredging convinced him that the Macclesfield Bank was by no means a "drowned atoll," but on the contrary that it was very much alive. The basis of the bank appeared certainly to be dead coral-rock, or in many places a calcareous rock composed of the consolidated vegetable organisms which seemed most common between the depths of 20 and 50 fathoms. Upon this ground corals grew in great patches, and other forms of life were very abundant, especially echinoderms, molluscs, crustaceans, and annelids; many very striking cases of mimetic resemblances were observed amongst them. Altogether forty-one genera of corals were dredged, excluding alcyonarian and hydroid corals; twenty-nine genera occurred between 25 and 35 fathoms, and twenty-seven genera in deeper water. It appears that reef-building corals can thrive at depths as great as 50 fathoms in the conditions of the Macclesfield Bank, where the water is very clear and warm. Concerning the genera represented, Mr. Bassett-Smith says:—

"The most universally distributed were *Seriatopora*, *Pavonia* (especially a variety of forms very nearly allied to *Mycedium elegans* of Milne Edwards), *Leptoseris Montipora*, and *Stylophora Güntheri*, at all depths, but the sections 'Madreporaria Fungida' and 'Perforata' are undoubtedly most frequently met with in depths over 20 fathoms, and continued down to between 40 and 50 fathoms; the corallum being almost always light and delicate. *Agavicia*, *Phyllastræa*, *Pachyseris*, *Turbinaria*, and *Leptoseris*, in cups of varying size, from two inches to twenty inches across; *Oxypora*, *Pavonia*, *Hydrophora*, *Scaphophyllia*, and *Montipora*, in leaf-like expansions; *Cyphastræa*, *Galaxea*, *Turbinaria* and *Montipora*, in encrusting growths; or in branching forms, as *Seriatopora*, *Mussa*, *Madrepora*, *Psammocora*, *Napopora*, *Anacropora*, *Alveopora*, and *Rhodaræa;* the most massive forms found in deep water being *Pocillopora*, *Stylophora* and *Mussa*. On the sandy bottom of the lagoon, and near the rim, the corals that seemed to thrive best were small branching forms of *Psammocora*, and *Anacropora;* delicate frond-bearing clumps of *Pavonia; Leptoseris* cups, thick but light spreading branches of *Alveopora*, *Montipora;* and many simple corals as *Cycloseris*, *Fungia*, &c. Small fragments of more massive *Astræa* were brought up three times from deep water, twice from 30 to 40 fathoms, and once from 40 to 50 fathoms."

There was a strong current over the rim, even in calm weather, and the surface water, the temperature of which was sometimes as high as 88° F., swarmed with Plankton.

In addition to the chart of the bank showing its unmistakable atoll form, the blue-book contains two sections of the outer slope on a natural scale. The angles varied somewhat on different sides. On the north the slope was gradual, the 100-fathom line being one mile distant from the 20-fathom line, while 200 fathoms was only found ten miles farther out, beyond which the slope became more rapid to 1100 fathoms six miles beyond. On the east there was a much steeper slope, the 100-fathom soundings being found half a mile from the 20-fathom and 300 at the distance of a mile, while fifteen miles away the depth was 2100 fathoms. The wall-like spring of the bank from the ocean floor is still more striking on the south, where depths of 150 fathoms occur half a mile from the edge of the bank, 300 fathoms at the distance of one mile, and the oceanic depth of 1100 fathoms, only 3⅓ miles away, giving the remarkably high average slope of 1 in 3. The shoal at the north end of the future island is attributed to the strong current from the south-west sweeping the débris over the edge of the oceanic hill into the deep beyond.

The observations fully confirm Dr. Murray's preference for the term "organic" rather than "coral" as applied to the origin of atolls, for a very large part of the growing rock was shown to be due to calcareous algæ, to corals other than reef builders, and to the accumulation of the calcareous remains of crustacea, mollusca and annelids. Mr. Bassett-Smith suggests that the crust of algæ prevents the dissolved carbonic acid of the sea-water from touching the dead coral rock below, while the action of the growing algæ might decompose the carbonic anhydride. This we are inclined to doubt, as the decaying organisms would seem likely to produce far more carbonic acid than could be disposed of by the very feeble daylight which reaches depths approaching 40 fathoms; and from the continual dredging of "rotten rock" in the central depression, we feel inclined to think that active life and rock-growth are taking place there only in restricted patches. The observations seem to leave no doubt that the atoll is growing towards maturity and the air, not declining from a past existence as an island.

HUGH ROBERT MILL.

[1] "China Sea. Report on the Results of Dredgings obtained on the Macclesfield Bank, in H.M.S. *Rambler*, Commander W. U. Moore, R.N., April 1888, and H.M.S. *Penguin*, Commander W. U. Moore, R.N., April 1892, and H.M.S. *Egeria*, Commander A. M. Field, R.N., April 1893." By P. W. Bassett-Smith, Esq., Surgeon R.N. (London: Printed for Her Majesty's Stationery Office, 1894.)

NOTES.

PROF. GEORGE FORBES, F.R.S., who has for the last three years been engaged on the utilisation of Niagara Falls, has, we understand, just returned to this country from the United States, the construction stage of the work being now completed. The close of the three years of Prof. Forbes's connection with the great work at Niagara Falls, which marks the change from the period of design and construction to the period of commercial activity in the existence of the Niagara Falls Power Company, forms a fitting opportunity for expressing the sense of gratification that all Englishmen, and the scientific world in particular, must feel in having had one of their countrymen chosen to undertake the important and difficult duties of electrical consulting engineer to an undertaking of such magnitude. The manner in which those duties have been discharged, and the pioneer services which Prof. Forbes has rendered them in respect of the work, have, we are in a position to say, received most gratifying testimony and cordial acknowledgment from his Company, who recognise in Prof. Forbes the scientific attainment, combined with independence of thought and action, which have been invaluable throughout the stage of operations now completed. Few realise the many novel conditions that have had to be met at Niagara Falls. But by dint of years of study of the many problems presented, Prof. Forbes has evolved a system which for completeness, adaptability, and security against breakdowns, had not been dreamt of before. The adoption of the alternating current before its value was fully realised by others, the initiation of the world in the use of a lower frequency than any that has hitherto been employed, and the remarkable confirmation of the foresight as to the economy of large transformers at high electric pressure, even at the low frequency employed, that has been established, are matters for congratulation. Although for fuller particulars of the system and apparatus employed, we must refer our readers to a previous account (NATURE, vol. xlix. p. 482), we may draw attention to the method by which Prof. Forbes met one of the most troublesome questions in connection with the design of the 5000-horse power generators (Fig. 1), arising in consequence of some requirements of the turbine designers—viz. the securing of a certain necessary momentum of the revolving part of the dynamo, without increasing the weight to be supported by the hydraulic piston in the turbine above a certain limit. The difficulty was met by fixing the armature, and revolving the field-magnet, formed of a nickel-steel ring with the pole-pieces pointing radially inwards, outside, the ring, or yoke, and the pole-pieces being supported by a bell-shaped cover fixed rigidly to the top of the vertical shaft from the turbine, the shaft being supported by bearings in the interior of the fixed armature. The foreseen ability to convert the alternating current into continuous current, and the low frequency into high frequency, which is

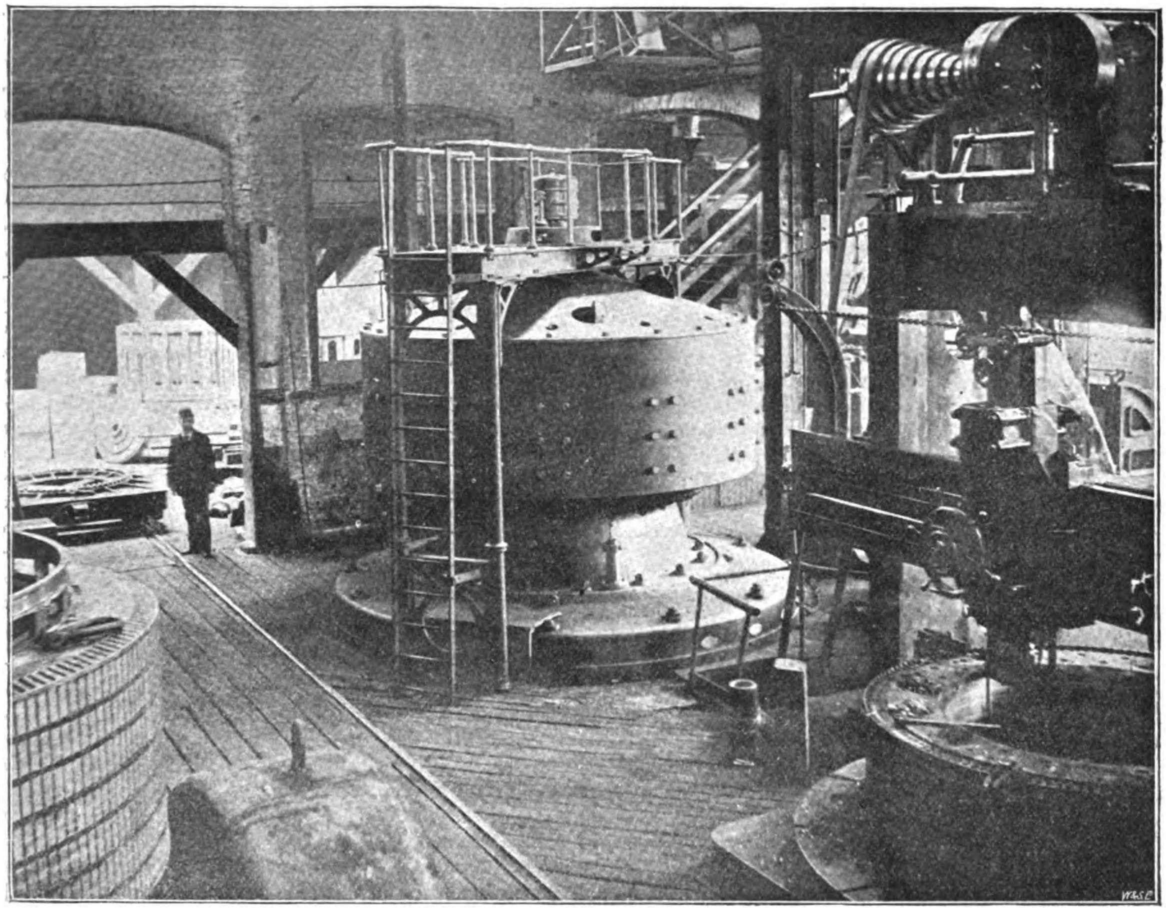

FIG. 1.

now realised in the invention of Messrs. Hutin and Leblanc, gives greater elasticity to the system; while the precautions taken to avoid sudden opening or closing of the circuits, gives a security against troubles experienced in the past by others such as has not obtained before. The success that has attended Prof. Forbes's efforts during the period of design and construction is of good augury for a successful issue to the commercial stage which the Niagara Falls Power Company now enters upon.

REUTER reports that a violent earthquake shock, lasting one minute, was felt at Oravicza, South Hungary, at 10.35 p.m. on December 19. Many houses fell in, while the walls of others were seriously cracked.

A BACTERIOLOGICAL Institute is about to be established in the University of Kieff (says the *British Medical Journal*), at an estimated cost of £10,000. A well-known druggist of Moscow has also given a house, valued at £3000, with £500 towards the fitting up of it as a bacteriological laboratory.

WE regret to record the death, on the 19th inst., of Prof. Allen Harker, of the Royal Agricultural College, Cirencester, at the age of forty-six. Mr. Harker was a popular and successful teacher, and did good work, not only at the College, but in connection with County Council technical education schemes, both in Gloucestershire and Bedfordshire.

THE Italian Botanical Society has decided to hold its annual meeting for 1895 in Palermo, in the latter part of April.

THE influence of the Royal Gardens at Kew upon other Botanic Gardens is strikingly shown in a list of the staffs of botanical departments and establishments at home, and in India and the Colonies, given in the *Kew Bulletin* (Appendix III.). Disciples have gone from Kew to the ends of the world to become directors or curators of Botanic Gardens; indeed, almost every Garden seems to have on its staff someone trained at Kew, or recommended by the Director there. A clearer testimony of esteem could not be desired.

FROM Mr. Carruthers's Report of the Department of Botany in the British Museum for 1893, we learn that the herbarium received some valuable additions during that year by gift and purchase. The most important were Mr. Deby's great collection of diatoms, numbering nearly 30,000 named slides; the late Mr. Jenner's collection of over 6000 specimens of algæ, a collection of over 1000 of the lower cryptogams of Dominica and St. Vincent, presented by the committee for the exploration of the West Indies; and a large number of flowering plants from Malaya, presented by Mr. Ridley.

A RAPID fall of the barometer on Friday, the 21st inst., made it clear that a serious disturbance was approaching our shores from the Atlantic, and by 6 p.m. of that day a "fresh" gale had already set in on the north-west coast of Ireland. During the night the centre rapidly crossed Scotland, and the whole of the United Kingdom experienced severe westerly gales, which occasioned great loss of life and property, and although the storm area subsequently crossed the North Sea, violent north-westerly winds continued during the whole of Saturday. The anemometer at Greenwich on Saturday morning showed a pressure of 29 pounds on the square foot, which is equivalent to a velocity of about 76 miles in the hour; but considering that the centre of the disturbance was at that time at least 400 miles to the north, there is no doubt that considerably higher velocities occurred in other parts of the country. In Scotland the barometer fell more than an inch and a half in 24 hours, and the subsequent rise was even more rapid.

WE have received two numbers of *Biology Notes*, a monthly pamphlet published by the Technical Instruction Committee of the Essex County Council. Under the direction of Mr. Houston the problem of reconciling the practical requirements of this district with a really scientific method of instruction in biology seems to be in rapid progress towards a satisfactory solution. Pioneer lectures are given, short courses for farmers and gardeners on such immediate topics as plant diseases, and systematic and largely practical courses of study in botanical science, at the Chelmsford Laboratory, and at various local centres. In addition, the Chelmsford Laboratory is rapidly becoming a centre for inquiry into, and the discussion of, agricultural problems. During the last three months the influence of ergot on gravid cattle, the toxic effect of bracken fronds, certain samples of foreign hay that had caused disease, and the distribution o potato disease, among other topics, have received attention. The combination of elementary instruction in science, on the one hand, with original inquiry on the other, and the practical simplicity of both departments of work, appear to us to be admirable features, and we would recommend it to the attention of those who are interested in Technical Education in similar districts in other parts of the country.

FIELD experiments of an instructive kind are carried on at the Royal Agricultural College, Cirencester, under the direction of Prof. E. Kinch. A pamphlet just received contains an account of experiments on oats grown this year on twenty-four plots differently treated. The general results were as follows:—The smallest yield of corn was from the plots receiving ammonium salts only, the unmanured plots, and the plots receiving cinereal manures only. The highest yield of corn was from the plots receiving fourteen tons of farmyard manure every year since 1885, followed by the plots receiving cinereals and mineral nitrogen, and phosphates and mineral nitrogen. The largest amount of straw was also given by the plots which had received the larger amount of farmyard manure annually, followed by those receiving mineral nitrogen with phosphates. The withholding of potash appeared to make little or no difference in the yield of straw, but the withholding of phosphates made a difference. The unmanured and cinereal manured plots gave the least straw. Experiments were also made to determine the crops of hay from twenty plots, to which different kinds and quantities and manures had been applied.

THE last issue of the *Zeitschrift für Physikalische Chemie* (vol. xv. part 3, p. 386) contains a paper by Messrs. Raoul Pictet and Altschul on "Phosphorescence at very Low Temperatures," which is of special interest in connection with recent work on this phenomenon. Glass tubes containing the sulphides of calcium, strontium, and barium were exposed to sunlight, and the duration and the extent of the phosphorescence were noted. The various tubes, after having been again exposed to sunlight, were plunged into liquid nitrous oxide, the temperature of which, by rapid diminution of pressure, could be brought to $-140°$. After twelve minutes' immersion the tubes were brought into a dark room, and their behaviour carefully observed. At first no indication of phosphorescence could be seen. In a few moments the upper part of the tube, which had not been so strongly cooled as the rest, began to phosphoresce, and gradually the feeble light seemed to spread itself down the tube, the lower part of which, however, glowed much more feebly than the upper. After five minutes the tubes acquired their ordinary vivid colour, without subsequent exposure to sunlight or even to diffused daylight. All phosphorescent substances appeared to behave in this way. Further experiments were then made in order to determine the limits between which these phenomena occurred. For this purpose a quantity of alcohol was cooled to $-80°$, and in it a tube containing some phosphorescent substance, after insolation, was immersed. That portion of the tube which was surrounded by alcohol in the outset glowed feebly, but in proportion as it took up the temperature of the cooled liquid its phosphorescence diminished, until at $-65°$ it entirely disappeared. The portion of the tube above the alcohol continued to phosphoresce strongly. After thirty minutes' immersion in the cooled alcohol, the tube was removed, and as it gradually acquired the temperature of the air, the lower portion began to glow. Before the glow—blue, green, or orange in colour, depending on the nature of the metallic sulphide—entirely disappeared, the colour became a faint yellow. It was found by comparative experiments that the alcohol exerted no specific influence on the results. These seemed to be entirely dependent upon the diminution or total cessation of molecular vibrations at the low temperature.

AN interesting paper on the Sicilian earthquakes of last August has recently been published by Dr. Mario Baratta (*Boll. della Soc. Geogr. Ital.*, Ott., 1894). The first shock of the series was felt on July 29 at Randazzo, and was succeeded by several other slight shocks, mostly in the Lipari Islands. Then came the severe earthquake of August 7 at 12h. 58m. p.m., and the still stronger one of August 8 at 5h. 16m. a.m. (Greenwich mean time). These affected chiefly the south-eastern slope of Etna, and were followed by more than twenty shocks in the same district, lasting until August 26. The meizoseismal area of the principal earthquake (August 8) is only about 7 km. long and 3 to 4 km. broad, and, as the intensity diminished rapidly outwards, it would seem that the focus cannot have been far from the surface. Moreover, the longer axis of this area runs north-west and south-east, and, when produced, passes through the central crater of Etna. It therefore probably coincides with a radial fissure of the cone, and indeed is not far, if at all, distant from that along which the eruption of 1329 took place. The pressure exerted by the column of lava in the central funnel, or by the forces which have raised it to its present height, may have caused such a fracture to be reopened. Thus, it is not impossible that the recent earthquakes indicate an unsuccessful attempt at a new lateral eruption.

FURTHER details relating to the same earthquakes are given in the *Bollettino Meteorico* (Suppl. 110) of the Geodynamic Office of Rome. The depth of the focus of the principal earthquake, according to Prof. Riccò, was about 4 km. The pulsations were recorded at Rome by the great seismograph, consisting of a pendulum 16 metres long, with a mass of 200 kg.; the first traces at 5h. 17m. 30s., and the principal maximum at 5h. 18m. 55s. The puteometer of the Observatory of Catania shows a trace about 21½ mm. long, indicating a temporary lowering of the well-water, which, in returning, stopped about 4 mm. below its original level.

THE additions to the Zoological Society's Gardens during the past week include a Yellow Baboon (*Cynocephalus babouin*, ♀) from Fort Salisbury, South Africa, presented by General Owen Williams; two Grisons (*Galictis vittata*) from Brazil, presented by Mr. H. A. Catlett; a Song Thrush (*Turdus musicus*), a Goldfinch (*Carduelis elegans*), British, presented by Mr. B. M. Smith; a Grenadier Weaver Bird (*Euplectes oryx*, ♂) from West Africa, presented by Lady McKenna; a Wild Cat (*Felis catus*) from Scotland, deposited; five Shore Larks (*Otocorys alpestris*), British, purchased.

OUR ASTRONOMICAL COLUMN.

ADVANCES IN LUNAR PHOTOGRAPHY.—MM. Lœwy and Puiseux recently communicated to the Paris Academy a paper on photographs of the moon, taken at the Paris Observatory, by means of the great Condé equatorial. Some of the photographs have been enlarged by Dr. Weinek, and the enlargements seem to have excelled in beauty and detail previous lunar pictures of a similar kind. An examination of the photographs shows that not only can they be used to verify the general features of the moon' surface, as depicted upon the most recent and complete lunar maps, but they also show a number of details and small craters which so far have been omitted from such maps. There are, of course, a number of causes which prevent a single photograph from being an ideal representation of a celestial object, and enlargements are usually regarded with a certain amount of suspicion, for there is always a possibility that interesting formations will be unconsciously manufactured in the process. MM. Lœwy and Puiseux know this as well as anyone; nevertheless, they find that the enlargements undoubtedly reveal new features, and definitely determine the existence of several contested objects. They think an instrument of long focus is essential for the best results, and that the enlargements should not be carried beyond twenty or thirty diameters. One object upon which the photographs have thrown light is the small isolated crater Linné, situated in the middle of the Sea of Senenity. According to Shroeter, Beer, Maedler, Lohrmann, and other selenographers, this crater was distinctly visible up to 1866, when Schmidt announced its disappearance. It was afterwards discovered again, but was much smaller than when described and figured by Beer and Maedler. Dr. Weinek finds that the object appears upon a plate taken on March 14, but only one kilometre in diameter—that is, about one-tenth the value assigned to it by the earlier observers. The crater has also been found on other plates, and Sig. Schiaparelli has testified to its reality. Four new objects—three craters, and the fourth an isolated elevation of some kind—have been found in the plain which extends to the south of Ariadaeus, between the bright crater-plain Cayley and the Silberschlag crater. Ten new craters can be detected in the typical walled plain Albategnius. All the rills observed to the west of Triesnecker can be seen to extend beyond the limits previously assigned to them, and to connect Ariadaeus, Hyginus, and Triesnecker with interlacing clefts. Judging from these results, we cannot but conclude that the photographs represent real advances in lunar photography.

COMETARY EPHEMERIDES.—The following ephemeris for Encke's comet is in continuation of that given on November 22, and is due to Dr. O. Backlund. M. Schulhof's ephemeris, in the *Astronomische Nachrichten*, No. 3267, is used for Swift's comet:—

	ENCKE'S COMET. *Ephemeris for Berlin Midnight.*		SWIFT'S COMET. *Ephemeris for Paris Midnight.*	
1894.	R.A. (app.) h. m. s.	Decl. (app.) ° ′ ″	R.A. (app) h. m. s.	Decl. (app.) ° ′ ″
Dec. 28	22 14 57	+3 35 18	0 3 23	−0 20 22
30	14 27	3 19 58	0 8 33	0 17 53
Jan. 1	13 52	3 3 38	0 13 41	+0 53 45
3	13 9	2 45 51	18 46	1 33 10

27	21 57	−8 47 28	17 26	8 25 4

It will be seen from these ephemerides that the two comets are in the same region of the sky, both being a few degrees south of Pegasus. Observations of the comets are greatly needed.

RUSSIAN ASTRONOMICAL OBSERVATIONS.—The latest *Bulletin* (vol. xxxv. No. 4) of the Imperial Academy of Sciences at St. Petersburg is almost entirely devoted to astronomical papers. E. Lindemann contributes a discussion of the visual and photographic magnitudes of Nova Aurigæ, and gives a light-curve extending from December 10, 1891, to April 13, 1892. N. Nyren discusses the observations made at Pulkova with the vertical circle, between 1882 and 1891, from the point of view of variations of latitude. The curves derived from the observations indicate that the interval between two maxima is 433 days, and between two minima, 434 days. As to the amplitude of the variation, though no definitive result is stated, the value of the radius of the circle described by the instantaneous pole appears to be 0″·145, and the direction of motion from west to east. Another paper on the sam e subject is contributed to the *Bulletin* by S. Kostinsky. In this case, the observations discussed were made with the great meridian instrument of the Pulkova Observatory, mounted in the prime vertical. The period obtained was 411 days, and the amplitude 0"·541. In addition to these papers, there is one on the orbits of Bielid meteors, deduced by M. Bredichin fro n o bservations made in 1892.

ON A REMARKABLE EARTHQUAKE DISTURBANCE OBSERVED AT STRASSBURG, NICOLAIEW, AND BIRMINGHAM, ON JUNE 3, 1893.

INTRODUCTORY NOTE.

THE Horizontal Pendulum.—The observations described in the subjoined article were made with the horizontal pendulum designed by Prof. Zöllner, and modified by Dr. von Rebeur-Paschwitz. This instrument consists of three thin brass tubes jointed together in the form of an isosceles triangle, the vertical angle of which is about 45°. The two equal sides are prolonged slightly beyond the base, and to the ends are attached two small spherical agate cups, the concavity of the lower one being directed from the centre of gravity of the pendulum, and that of the upper one towards it. When the pendulum is placed in position, these cups rest on two steel-points attached to the stand of the instrument and directed normally to the surfaces of the agate cups. One steel-point is almost exactly above the other, so that the axis of rotation is nearly, but not quite, vertical, its inclination to the vertical being still great compared with the movements of the ground we wish to investigate. The pendulum rests in the vertical plane passing through the axis of rotation, and on the side towards which it inclines. If this is towards the east, and if the axis is slightly tilted in the east and west plane, there will be no deflection of the pendulum; the only change will be in its sensitiveness. But if the axis is tilted in any other plane, it will no longer incline towards the east, and the pendulum will be deflected from its original position, in order to remain in the same vertical plane with the axis of rotation. It is evident that the smaller the original inclination of the axis to the vertical, the greater will be the deflection for a given tilt of the axis in the north and south plane; that is, the greater will be the sensitiveness of the pendulum.

From the middle of the nearly vertical tube of the pendulum, there projects outwards a small bar. Passing through an aperture in the frame to which the steel-points are attached, this bar carries a mirror, whose plane is at right angles to that of the pendulum. A ray of light, proceeding from a fixed source, is reflected by the mirror, and registers the movements of the pendulum on a strip of photographic paper wrapped round a revolving drum. The zero-line is traced by a ray of light reflected by a fixed mirror just below the other, and attached to the stand of the instrument.[1]

Observation of Earthquake Pulsations.—Nothing could show better than Dr. von Rebeur-Paschwitz's interesting paper how desirable it would be to have a few well-chosen stations in different parts of the world where these pulsations could be registered. They might then be traced as they spread out from the origin of a great earthquake, and might even be followed, as he suggests, in their course, completely round the world.

In several Italian observatories there are established instruments suitable for this purpose. Horizontal pendulums, with recording apparatus, are now at work at Charkow and Nicolaiew in the south of Russia; and two others will soon be ready at Strassburg and Merseburg in Germany. A bifilar pendulum[2] at Birmingham, belonging to the British Association, will shortly be furnished with a photographic recorder. Thus Europe is at present fairly well provided for.

A large number of stations in other parts of the world is by no means absolutely necessary. Results of great value would be derived if recording instruments were erected at places near the east and west coasts of North America, in South America, South Africa, India, Australia or New Zealand, and the Sandwich Islands. In Japan Prof. Milne's tromometer[1] leaves little to be desired.

The chief element to be determined is the exact epoch of the beginning, maximum amplitude, and end of the pulsations, or of each group of pulsations. The horizontal pendulum, Dr. von Rebeur-Paschwitz informs me, can be arranged so that its sensitiveness for slow tilts of the ground can be diminished without necessarily lessening its sensitiveness for earthquake shocks. The strip of photographic paper can thus be reduced in width without running any risk of the spot of light leaving the paper during its ordinary daily and other movements. Without increasing the expense, a more rapid movement of the paper could be permitted, and this would enable the determination of the time to be made with greater accuracy. Possibly, also, the construction of the instruments might be simplified if earthquake-pulsations are to be the principal subject of investigation. In the bifilar pendulum, for example, since the amplitude of the oscillations is a point of minor importance, the somewhat elaborate machinery for determining the angular value of the scale divisions might be dispensed with, and also the arrangements for readjusting the spot of light from a distance.

Hardly less important in these investigations is the determination of the exact time of occurrence of the earthquake at or near its centre of disturbance. But on this it is the less necessary to insist, for in so many of the more marked seismic districts there now exist organisations for the study of earthquakes. It may not be out of place, however, to suggest that in all seismic records, and in every part if periodically published, the standard time employed should be clearly stated. It is not universally known, for instance, that, in Japan, Tokio time was replaced on January 1, 1888, by the time of 135° E. long. In accounts from Beluchistan, again, we cannot be certain whether Madras time or railway time is meant, for both are used. The trouble of inserting this important detail is hardly to be compared with the confusion and error that may result from its omission.

C. DAVISON.

IN the last report of the Earth Tremor Committee of the British Association, reference is made to an observation of earth-pulsations by Mr. C. Davison on the evening of June 3, 1893, at Birmingham, which was obtained by the aid of Mr. H. Darwin's bifilar pendulum. I take the following details from the report:—At 5.43 p.m. (G.M.T.) the image was found to be perfectly steady, but at 6.29, when the observer returned to the cellar, it was moving slowly and steadily from side to side of the field of view, thus indicating the passage of a system of earth-waves. At 6.42 the image had come to rest, but at 6.46 the oscillations commenced again, and continued to be visible with varying amplitude until 8.13. After 8.13, though the observer watched for two hours and a half, no further motion was noticed. The period of the waves was found by a number of observations to be between fifteen and twenty seconds, and the range of motion at its maximum one-eighth of a second.

Mr. Davison's observation is especially interesting, because it corresponds exactly with a *very extraordinary disturbance* which was registered by the horizontal pendulums at Strassburg and Nicolaiew. Amongst the considerable number of disturbances common to both these places, that of June 3 is certainly the most prominent during the interval from January 1 to September 4, 1893. In the accompanying illustration (Fig. 1) the two curves, obtained by photography, are shown side by side; in correspondence with the difference of longitude between the two places, the lower curve was moved 17·5 mm. to the left. The pendulum in both cases was placed in the east-west plane. In the following notes the time is Greenwich Mean Solar Time, and is given in decimal parts of the hour.

(*a*) *Strassburg.*—The disturbance begins suddenly and small at 4·42, the curve having been perfectly sharp and steady before. The range of motion increases to 4 mm. at 4·52 and decreases at 4·69. It then again increases so as to make the curve disappear entirely between 4·77 and 5·05. During the interval the light-point was displaced by 3½ mm. to the north, which corresponds with a deflection of the pendulum towards the south. At 4·82, the person who keeps control over the instrument entered the cellar, to look after it and to determine the time correction, which is done by shutting off the light during

[1] For a fuller account of the horizontal pendulum, see Dr. von Rebeur-Paschwitz's great memoir, "Das Horizontalpendel" (*Nova Acta der kais. Leop. Carol. Deutschen Akademie der Naturforscher*, Bd. lx. 1892, pp. 1-216); also Brit. Assoc. Rep., 1893, pp. 303-308.

[2] NATURE, (July 12, 1894), vol. 50, pp. 246-249; Brit. Assoc. Rep., 1893, pp. 291-303.

[1] Brit. Assoc. Rep., 1892, pp. 107-109.

a known interval of five minutes. He then locked the cellar, and when he returned at 8·45 he was obliged to make a correction,[1] because the light-point had left the paper. Unfortunately, he forgot to note down its exact place, but from the inspection of the curve it is evident that at 5·61, after a short interval of steadiness between 5·25 and 5·61, the pendulum received a sudden shock, which caused it to oscillate, and at the same time produced a deflection, by which the light-point was probably brought off the lower edge of the paper, from which it was distant 48 mm. at the time of the shock. There can be no doubt that such was the cause of the disappearance of the curve, for the base-line runs on perfectly undisturbed, which is a sign that the instrument continued to be in good working order, as usually. From 8·45 to 9·65 the motion is small; and from 9·65 till 11·16 the curve is nearly perfectly steady.

At 11·16 a new disturbance begins; the range of motion is very small at first, but increases to 5 mm. at 11·45, and to 10 mm. at 11·60; at 12·10 the disturbance, which is much like the first one, comes to an end, and is again followed by a steady part of the curve.

At 12·26 commences the last disturbance, which at 12·47 increases to 6 mm. Between 12·73 and 13·03 no traces of the curve are visible, and during this interval a displacement of 10½ mm. has occurred, which indicates a deflection of the pendulum towards the north. The motion continues to be visible until 14·45; the curve then resumes its nearly steady appearance, which is once again interrupted by small motion at 14·95.

(*b*) *Nicolaiew.*—The following details were communicated to me by Prof. Kortazzi, who informed me that on this day he went down into the cellar one half-hour later than usually, at 6·54, when he found that the light-point had passed from the paper on to the brass rod, which serves to clamp the paper, and was swinging considerably. From this reason the light-point could leave no traces on the paper between 5·95 and 6·62. The disturbance is very large and of long duration. It commences at 4·32 and reaches its first maximum at 4·80, when the range is >60 mm. Strong motion continues until 8·4. From the copy of the disturbance, which Prof. Kortazzi kindly sent me, and which is represented in the above figure, it appears that at about 5·77, or ·11m. *before* the light-point was prevented to trace a curve, by passing on to the brass rod, the curve was suddenly interrupted, which shows that the pendulum was performing large oscillations. Between 9·72 and 11·05 the motion is small. At 11·05 a new disturbance begins, which increases suddenly at 11·36, diminishes a little at 12·3, and increases again at 12·47 From 12·7 to 13·22 no traces of the curve are visible. At 13·9. the motion decreases considerably, and after another small increase at 14·87 reaches its end at 15·17.

The figure shows that the motion at Nicolaiew is much more considerable than at Strassburg. Whilst at the latter place the whole disturbance is divided into four distinct parts, which are separated by moments of nearly perfect steadiness, at Nicolaiew the first and second, as well as the third and fourth part, each form a continuous disturbance.

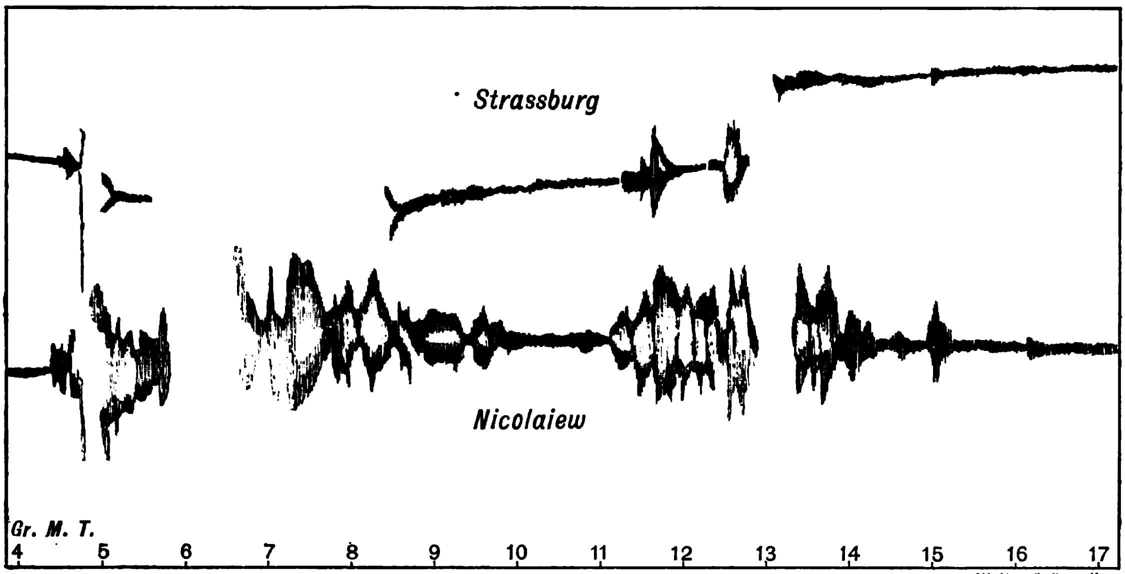
If we denote by V the relative strength of a shock in a direction normal to that of the pendulum, by α the range of motion, measured on the curve, by d and T the distance between the photographic drum and the pendulum mirror, and the period of oscillation of the pendulum, then we have the following relation between the observations in two different places:—

$$\frac{V_1}{V_2} = \frac{\alpha_1}{\alpha_2} \cdot \frac{d_2 T_2}{d_1 T_1}.$$

In the present case

$$d_1 = 1·8\text{m.},\ d_2 = 4·6\text{m.},\ T_1 = 17·0\text{s.},\ T_2 = 10·2\text{s.},$$

thus $\frac{d_2 T_2}{d_1 T_1} = \frac{47}{31}$. A shock of the same strength therefore produces at Nicolaiew a disturbance 1½ times as large as at Strassburg.



Walker & Boutall sc.

FIG. 1.—Earthquake Disturbance observed at Strassburg and at Nicolaiew on June 3, 1893.

In comparing the two curves, it is evident that the different intensity of motion at the two places is not due to the difference in the values of the instrumental constants. The reason why the motion of the pendulum is so much stronger at Nicolaiew is this, that the soil consists down to a great depth of sand, which is particularly favourable for the development of strong motion. In this respect Nicolaiew resembles the two former stations, Potsdam and Wilhelmshaven. Many facts tend to show that the soil at Strassburg, though often disturbed by small earthquakes of distant origin, never oscillates as much as at the forenamed places. It would not be right, therefore, from the mere look of the curves, to draw the conclusion that the earthquake—if such was the cause of the disturbance—must have originated at a place considerably nearer to Nicolaiew than to Strassburg.

Until now I have not been able to find a record of a phenomenon which might possibly be connected with this disturbance. From its size and duration, one ought to think that it must have been caused by a strong catastrophe, surpassing anything that has been reported during the last year from all parts of the world. But it is strange that the magnetic recording instruments at Potsdam have shown no trace of motion, and that nothing is reported from the delicate seismological instruments which are at work in Italy.

[1] In the original photograph the second part of the curve is much displaced, in the same way as the third part after the interruption. This was altered in the figure to economise space.

The case is remarkable in more than one respect. Displacements of the light-point, which, though the oscillations of the pendulum were much larger generally, were scarcely noticeable during the former observations with this instrument at other places, often occur at Strassburg. I am inclined to think that they are due to a vibratory motion of the ground, which scarcely affects the motion of the pendulum, but may cause a change in its position with regard to the steel pivots. These vibrations appear to be more easily propagated by the soil at Strassburg than at Nicolaiew, for though small displacements occasionally occur at the latter place, they are considerably smaller. This is particularly evident in the present case, where the only displacement worth mentioning is connected with the shock at 5·77. On the other side, the displacement at Strassburg, which produced the long break in the curve, is far the largest that occurred during one and a half years' observation. It is much larger than that which took place when an iron hook was driven into the pillar on the side opposite to the pendulum.

Our figure shows that the displacements of the pendulum were comparatively larger during the first and second than during the third and fourth disturbance. The change during No. III. is about 1 mm. Another fact worth noting is that in the two first cases the pendulum is deflected towards the south, and in the two last towards the north. This seems to indicate, if one considers the special arrangement of the instrument, that the motion arrived from the north in the first and second, and from the south in the third and fourth case. The displacement of the pendulum at Nicolaiew at 5·77 is also directed towards the south, in accordance with the observation at Strassburg.[1] The above conclusion is founded on the supposition that the displacement is produced by a *single* shock, which causes the steel-points connected with the stand of the instrument to slip on the agate cups. In reality, the motion is probably much more complicated, and perhaps one is not justified in supposing the direction of the shock to be opposite to the deflection of the pendulum. The comparison of the observed times, indeed, leads to a different result.

The following table gives a summary of the observations:—

Again the times of disappearance of the curve or of maximum motion are separated by nearly the same interval, viz., at Strassburg III.–I. = 6·83h., IV.–II. = 7·12h.,[1] and at Nicolaiew IV.–II. = 6·9h. The duration at Strassburg of No. I. is 0·83h., and of No. II. 0·94h.; the duration of No. III., if we omit the last part, in which the motion was very small, is 2·84h., of No. IV. 2·69h. At Nicolaiew, during the first half of the disturbance, the strong motion ends 4·08h. after the beginning, and the second part lasts 4·12h. The intensity of I. and II. is evidently larger than that of III. and IV.

We will now see if the direction of motion can be determined by the observations.

I. Though the first trace of motion is 0·10h. earlier at Nicolaiew than at Strassburg, yet it is probable that the corresponding moments are those of the disappearance of the curve at Strassburg and of maximum oscillation at Nicolaiew, or 4·77h. and 4·8h. To judge from the copy, which Prof. Kortazzi sent me, the latter value is only approximate. The difference in time is certainly small, and the direction of the motion remains rather uncertain; the general aspect of the figure, however, makes it more probable that it came from the east.

II. The time of disappearance of the curve at Strassburg, 5·61h., is probably correct within 0·02h. or 0·03h. Mr. Davison's observation shows that the motion, which in this case appears to have commenced suddenly, had not reached Birmingham[2] at 5·72h.; on the other hand, the disappearance of the curve at Nicolaiew took place at 5·8h., or about 12m. later than at Strassburg. If these times were all correct, and if the three moments really corresponded with the same phase, the centre of disturbance ought to be looked for somewhere at the south-west and not too far away from Strassburg. This, however, is a very improbable result. Mr. Davison's instrument could only indicate an east-west tilt, and perhaps the motion had already set in when he left the instrument at 5·72h., but was not perceptible enough in the east-west direction.[3]

The two other observations make it nearly certain that the motion arrived from the west.

III. The case is very much like No. I.: probably the motion arrived at Nicolaiew first, but its direction cannot be determined with certainty.

Disturbance	Strassburg.	Nicolaiew	Birmingham
No. I. (displacement − 3·5mm)	h. 4·42 first trace 4·52 increases 4mm. 4·69 decreases and increases again 4·77 curve disappears 5·05 reappears 5·25 end } curve steady during the interval	h. 4·32 first trace 4·8 first maximum>60mm.	
No. II. (displacement probably >−48mm.)	5·61 new shock 8·45 } light point corrected 9·65 } motion small } nearly steady 11·16	5·8 curve disappears strong motion 8·4 9·72 } small motion 11·05 }	h. 5·72 the image was found to be steady 6·48 strong motion 6·70–6·77 steady again 8·22 end
No. III. (displacement + 1mm.)	11·45 first increase 5mm. 11·60 second increase 10 mm. 12·10 end } curve steady 12·26 first small motion }	11·36 sudden increase 12·3 diminishes	
No. IV.[1] (displacement + 10.3mm.	12·47 increase 6mm. 12·73 curve disappears 13·03 reappears } motion small 14·45 } 14·95 new small increase	12·7 curve disappears 13·22 ,, reappears 13·97 decrease of motion 14·87 new increase 15·17 end	

When looking over these figures, one is inclined to think that the remarkable correspondence between the several phases of the disturbance cannot be due to chance. If we take as the beginning of a disturbance the moment when its first traces are visible, we have the following differences at Strassburg:—II.–I. = 1·19h. and IV.–III. = 1·10h., III.–I. = 6·74h., IV.–II. = 6·65h. At Nicolaiew, where I. and II., III., and IV. appear as a single disturbance each, we have III.–I. = 6·73h.

[1] In the figure the curve is displaced in an opposite direction, but this is the case because the drum stands west of the pendulum at Nicolaiew, and east of it at Strassburg.

[1] The beginning of II., though sudden and sharp, need not necessarily coincide with the movement of greatest motion; in this case the difference IV.–II. would have a smaller value.

[2] The distance between Strassburg and Birmingham is about 800 kilometres.

[3] [Much weight cannot be attached to the absence of observed motion at Birmingham at 5·72h. The image of the wire was adjusted on the cross-wire of the telescope without difficulty, and must have remained practically in contact for a few seconds. A small movement, with a period so long as twenty seconds, might easily at this time have escaped notice.—C. D.]

IV. The curves again disappear at about the same time; but to judge from the time of greatest steadiness before the disturbance commenced at Nicolaiew, it appears to have reached Strassburg first. The last small increase at 14·87h. and 14·95h. is, on the contrary, earlier at Nicolaiew than at Strassburg, but this might be an independent disturbance. After the strongest motion, the light-point resumes its steadiness much sooner at Strassburg than at Nicolaiew.

It is evident that the case is, on the whole, not favourable to an hypothesis which first occurred to me, that all four disturbances might have been caused by four successive waves emanating from a single centre and a single shock, and circulating round the earth. The fact that II. and IV. are more considerable than I. and III. does not appear of much importance, for it is proved by many examples that the intensity of a disturbance is not alone dependent from the distance from the centre; but, if the hypothesis were right, disturbances III. and IV. ought probably to be much smaller. Besides, the velocity of about 100 km. per minute would be a very small value compared to those determined on other occasions.

I reject this hypothesis, but I do not think it improbable that I. and II., III. and IV. may be connected in the way just mentioned, and that both disturbances came from the same part of the world. It is the principal object of this communication to induce persons interested in the subject to study carefully the records of all self-registering instruments. If the disturbance originated at the bottom of the sea, something about it might be found in the ship journals, the tidal records might show a trace, or perhaps the magnetical records at distant places. I have many proofs that the size of a disturbance, traced by the horizontal pendulum, is not always a measure for the importance of the catastrophe which produced it; but in the present case many instances indicate an extraordinary phenomenon, of which an account is likely to appear sooner or later, in case it should have taken place at some remote corner of the earth.

Merseburg, May 18.

P.S.—Some time after having written the above, I received the third volume of the *Seismological Journal of Japan* (1894), in which there is an interesting paper by F. Omori on the eruption of Azuma-san in 1893. From this paper it appears that the volcano was in an active state since May 19, when an explosion took place, which was followed by two other ones on June 4, 1.10 a.m., and on June 7, of which the former is said to have been the strongest. It was accompanied by an earthquake, which was felt at the meteorological station of Fukushima. Supposing the above time to be Standard Time (9h. east of Greenwich), the explosion took place at 7h. 10m. p.m. G.M.T. on June 3, and thus it is seen that it coincides with a part of our great disturbance. I do not, however, believe that this is more than a casual coincidence, for the two other eruptions produced no disturbances. It is also a well-known fact that volcanic eruptions, even when accompanied by earthquakes, are generally not felt to any great distance, unless they bear a very violent character, like the eruption of Krakatoa; but from Mr. Omori's description it appears that the eruption of Azuma-san was nothing very extraordinary. I therefore believe that we must wait to find another explanation for our disturbance.

E. VON REBEUR-PASCHWITZ.

EXPLOSIONS IN MINES.

IN a lecture on some modern developments in explosives, given at the Society of Arts on December 17, Prof. Vivian B. Lewes threw out a suggestion as to the cause of explosions in dusty mines free from fire-damp, which explains the anomalies which have presented themselves in several recent explosions.

It was pointed out that until quite recently explosions in mines were always attributed to the accidental ignition of mixtures of air and methane, to which the name of "fire-damp" is given, and undoubtedly this cause is the prime factor in this class of disaster, and the introduction of such precautions as safety-lamps at once brought about a considerable reduction in the number of explosions taking place. Many disasters, however, still continued to occur under apparently mysterious circumstances, the conditions being such that any large proportion of methane in the air of the mine appeared practically impossible, but investigations of such explosions showed that coal-dust in a dry and finely powdered condition had generally been present in the mine at the time of the explosion, and the coked residue of this dust was found afterwards on the surface exposed to the explosive wave, and years of experimental investigation by scientific men of the greatest ability proved the fact that air containing so small a proportion of methane as to be itself perfectly non-explosive, becomes a good explosive again when holding dry and finely divided coal-dust in suspension, and within the last few years explosions having taken place in mines, which have always been celebrated for their freedom from any trace of methane. Further experiments have been made by Mr. H. Hall and Mr. W. Galloway, who have shown that the violent ignition of dust-laden air is possible by a blown-out shot, even if free from any trace of marsh gas, and there is evidence to show that the explosion is developed in throbs or waves.

It is therefore found that the explosions in mines may be brought about, first, by the ignition of a mixture of methane and air, in which the former rises above a certain percentage; secondly, by mixtures of air, coal-dust, and methane, in which the amount of the latter may be excessively small; lastly, by mixtures of coal-dust and air. With regard to these explosions caused by coal-dust and air alone, the Royal Commission on Explosions from Coal-Dust in Mines, in their second report, published this year, say:—

"On a general review of the evidence on this point, we have no hesitation in expressing our opinion that a blown-out shot may, under certain conditions, set up a most dangerous explosion in a mine, even where fire-damp is not present at all, or only in infinitesimal quantities; and while we are prepared to admit that the danger of a coal-dust explosion varies greatly according to the composition of the dust, we are unable to say that any mine is safe in this respect, or that its owners can properly be absolved from taking reasonable precautions against a possible explosion from this cause. But even if we had been able to come to a different conclusion, and to agree with the minority of the witnesses examined, who think that coal-dust alone cannot originate an explosion, we should still have to call attention to the serious danger which results from the action of coal-dust in carrying on and extending an explosion which may originally have been set up by the ignition of fire-damp."

One of the most interesting and instructive explosions which have taken place recently was that which occurred a little more than a year ago at the Camerton Collieries, Somersetshire, in which as far as investigation could go, no trace of combustible gas could be found in the mine at any period prior to the explosion or subsequent to it, and in which everything pointed to the explosion being entirely due to the presence of dry coal-dust in the air.

Of absorbing interest, also, are the experiments made by Mr. Hall at the latter end of 1892 and the early part of 1893, and reported upon by him to the Secretary of State on January 23, 1893, in which he shows by conclusive experiments that dry coal-dust under conditions frequently present in coal mines and in the entire absence of fire-damp, may be inflamed by a blow-out gunpowder shot, and cause a disastrous colliery explosion.

The evidence which can be collected from the investigation in the Camerton disaster, and from Mr. Hall's experiments, point to a cause for such explosions, which has apparently been overlooked, and which Prof. Lewes thought worthy of the gravest attention. Both at the Camerton Colliery and in Mr. Hall's experiments, powder was the blasting agent used, and such powder as is employed for this purpose, gives amongst the products of combustion nearly half the volume of permanent gases in the condition of carbon monoxide, methane, and hydrogen.

In the Camerton explosion, it seems probable that about 1¼ lbs. of such powder were used in the shot which caused the disaster, and this quantity of powder would give, roughly, a little over three feet of inflammable gas, which when mixed with pure air would give over 10 cubic feet of an explosive or, at any rate, rapidly burning mixture, and experiments which have been made upon the effect of fire-damp and dust combined in causing colliery explosions show conclusively that even when the fire-damp is present in such minute quantities as to form a mixture very far removed from the point of explosion, it still makes the mixture of coal-dust and air highly explosive; and from experiments which Prof. Lewes has made, it is clear that traces of carbon monoxide will do exactly the same thing when the air is laden with coal-dust, whilst the temperature of ignition is slightly lower than with methane, so that in the case of the Camerton Colliery, it being perfectly well ascertained that the air was charged with coal-dust, the probabilities are that not 10 feet, but a far larger volume of explosive mixture was formed by the rapid escape of the products of combustion into the coal-laden air; and this being ignited, either by the flame or red-hot solid products driven out into it by the blown-out shot, would initiate a considerable area of explosion.

The classical researches of Prof. H. Dixon have shown that hydrocarbons and, probably, carbon burn in air to carbon monoxide, and that this carbon monoxide will not form explosive mixtures with air, or even with oxygen, if they are absolutely dry; but if water vapour is present, they explode owing to the oxidation of the carbon monoxide to dioxide, causing the propagation of an explosive wave, which reaches its maximum velocity when the percentage of water vapour, between 5 and 6 per cent., and inasmuch as the air of the mines would always contain some moisture, and as the products of combustion also would give a large volume of water vapour, these requirements would be amply fulfilled.

Still more conclusive on this point were Mr. Hall's experiments. In these a charge of blasting powder was fired from a cannon suspended in a shaft, the air of which was proved by careful chemical analysis to be absolutely free from any trace of combustible gas.

In order to get some idea of the condition of the air inside the pit during the explosion, samples of air were taken and were analysed. Two brass tubes were fastened to the rope that was used to lower the cannon, one twenty yards from the bottom, the other forty yards from the bottom.

These tubes were so arranged and constructed that the explosion, as it passed the tubes, unsealed the outlet pipe, and the escaping water sucked in a sample of air which was trapped by a special arrangement, and kept in the tube until the rope could be wound up. By this method it was intended that the sample of gas taken should represent that state of the air whilst the flame was passing, or directly afterwards.

The tube nearest the bottom, as the analysis will show, did partly collect the gas in the above condition. The tube at the top, however, commenced to act prematurely, and was probably started by the sound wave which preceded the explosion. This tube simply contained ordinary air.

The following is an analysis of the gases found in the lowest tube:—

	Per cent.
Oxygen	3 9
Nitrogen	75·9
Carbon dioxide	12·1
Carbon monoxide	8·1
	100·0

This ingenious arrangement was due to Mr. W. J. Orsman, and it is probably the first successful attempt which has been made to get a sample of gas during the progress of explosion, and there is not the slightest doubt that the presence of such an amount of carbon monoxide converts mixtures of coal-dust and air into a highly explosive body.

As the explosion takes place, and as the carbon monoxide ready produced is oxidised to carbon dioxide by the action upon it of water vapour present, and also by its direct combustion with oxygen, the hydrogen of the water vapour is set free, whilst the heated coal-dust also yields certain inflammable products of distillation to the air, and partial combustion also of the coal-dust gives a considerable proportion of carbon monoxide once more, and these driven rapidly ahead of the explosion form with more coal-dust and air a new explosive zone, and so by waves and throbs the explosion is carried through the dust-laden galleries of the mine.

The experiments made by Mr. Hall, and investigations in various colliery explosions, make it abundantly manifest that no explosive should be licensed for use in mines unless it can be absolutely proved that it gives off no imflammable products of combustion. The following table will show the results given by some of the explosives most largely used, which point very clearly to the fact that, with the exception of the Sprengel explosives, such as roburite and nitroglycerine, none of the bodies in use conform to this important requirement.

Products of Combustion of Blasting Explosives.

Powder.	Carbon dioxide.	Combustibles. Carbon monoxide.	Combustibles. Hydrogen and marsh gas.
Gunpowder ...	50·6	10·5	3·1
Blasting power ...	32·1	33·7	7·9
Sprengel explosives—			
Roburite	32·0	nil	nil
Ammonite ...	33·0	nil	nil
Nitroglycerine explosives—			
Nitroglycerine ...	63·0	nil	nil
Gelignite	25·0	7·0	nil
Carbonite	19·0	15·0	26·0
Blasting gelatine ...	36·5	32·3	8·6

Whilst not only these considerations, but Mr. Hall's experiments, point to the absolute necessity of legislative enactments at once forbidding the use of blasting powder in any coal mines, no matter how free they may appear to be from fire-damp or from dust, if the returns made as to deaths caused by gunpowder and other explosives in mines for the year 1893 are examined, it will be clearly seen that the exclusion of gunpowder, in handling alone, would do away with 80 per cent. of the accidents. So that if explosives of the Sprengel class were employed, accidents due to the explosives used would be practically eliminated from the mining death roll; and it is only a question of time as to when England will follow the action of France and Germany in altogether prohibiting the use of blasting power in dusty mines.

THE POSSIBILITIES OF LONG-RANGE WEATHER FORECASTS.[1]

If we had perfect command of this subject, we should be able to trace the motion of a particle of aqueous vapour from point to point over the whole earth, and could predict whether at any time in the future it will fall as rain, or rise and fly away as an invisible gas. In the absence of this higher knowledge the only long-range forecasts that we are at present able to make are based upon empirical and very imperfect rules deduced from our study of the accumulated climatological statistics. Of course, such predictions do not imply any special knowledge of meteorology. Among the methods adopted in long-range forecasts are the following:

(*a*) The average rainfall, temperature, &c., for any period, such as a month, and deduced from many years of observation, is called the normal. The excess or deficiency of this month in any given year is called the departure for that year. A general prediction may be made to the effect that the rainfall for a given month and place may be expected to lie within the range of the values indicated by these known departures.

(*b*) The series of annual or monthly values just mentioned gives us the means of finding out whether there is any simple sequence or connection between them and the apparently unconnected values that occur from year to year. Thus, it sometimes happens that rainy seasons come after two or three dry seasons, or that after the same month has been dry in three successive years, one is then justified in predicting a wet month. Thus, Governor Rawson elaborated a system for the prediction of rain and the sugar crop in Barbados.

(*c*) Slight but appreciable widespread, rather regular fluctuations of temperature, pressure, and rain have been revealed in the climate of Europe by Dr. Brückner, who finds that a deficient temperature and an excess of rain have alternated with excess of temperature and deficiency of rain in periods of thirty-six or thirty-seven years during the past two or three centuries; the glaciers increase and diminish in volume, or advance and retreat, in correspondingly regular but somewhat retarded intervals. Predictions may be based on these well-established periods.

(*d*) Droughts are sometimes due to what happens in distant regions: thus, if there is a heavy snow on the Himalayas during the winter, there is a special liability to drought in lower India in the following summer, so that the prediction of a drought may be based upon the reports of snow-fall in a distant region several months before the drought occurs; but other droughts may occur without this preliminary snow-fall. This connection

[1] Reprint of an article contributed by Prof. Cleveland Abbe to the U.S. *Monthly Weather Review*.

is, so far as at present known, a local, arbitrary, or accidental one, and has not yet been found to recur in any other portion of the globe.

(*e*) Droughts or floods may occur every year in some portion of an extensive region, so that it may become possible to predict the occurrence in a special section one year because one has occurred in another section a previous year. Thus, a serious drought in the lower Indian peninsula has, on five occasions, been followed by one in northern India the next year.

(*f*) If we had maps of the weather of the whole globe for every month for a long series of years we should, undoubtedly, be able to find many similar coincidences, so that a drought for a given section might be predicted from the rain-fall, the snow-fall, the temperature, the pressure, or other conditions in a distant part of the globe. As a rule, important climatic crises are the results of changes that have been going on slowly for a long time in distant parts of the earth. The general circulation of the air constitutes a complex system in which the areas of high pressure and dry clear air are the results of slowly descending winds moving toward the equator; the general rains are formed wherever a descending current of air, a mountain range, or other obstacle has an opportunity to push up the moister air of the earth's surface. From this point of view rainy and dry and cold and hot seasons depend largely upon the varying relations of the upper and lower currents to the continents and even to each other. The long-range prediction of the climate of any season must depend upon the prediction of the general character of the horizontal and vertical movement of the air. In our present geological epoch the continents are permanent features, and we consider only the changes that take place in the atmosphere, but in studying the climatic changes of earlier geological epochs we have to consider the changes in elevation of the continents themselves.

(*g*) Such apparent connections as that between snow-fall on the Himalayas and the subsequent drought in northern India are not to be thought of as cause and effect respectively. It might be argued that the layer of snow must be evaporated, or melted, thereby absorbing more heat than would have been required if it had fallen as rain and rapidly drained away; but this cooling influence is distributed over many weeks, and through the immense quantity of air that has passed over the snow-fields during the winter and the spring, and is thereby rendered too slight to have any great local influence in India. A broader view of the subject shows us that the winter snow-fall and the summer drought are simply two features of an extensive system of changes in which the whole atmosphere of the earth takes part. The whole globe may be divided into regions where the lower stratum is moving either horizontally or upward or downward, and where the upper stratum has similar diversities of movement. These systems of motion determine whether we shall have fair weather or rain, hot weather or cold, from day to day and accumulatively from month to month. Now these three movements are related to each other in such a way that the sum total of the energy involved throughout the atmosphere is sensibly constant, while the localities at which the upward and downward motions are taking place are undergoing perpetual changes.

The centres of high pressure over the oceans and continents slowly sway east and west or north or south; the paths of the storm-centres vary in a similar manner to suit the changes of these larger areas, and the centres themselves move rapidly or slowly in response to these same changes. The air that ascends between the northern and southern tropical regions of high pressure descends sometimes in high latitudes, giving them cold weather with rain or snow; at other times in low latitudes, giving them warm weather with droughts. It matters not whether the droughts in southern regions chronologically follow or precede the snows of the northern regions; in neither case can either one be spoken of as the cause of the other, but each is in its turn the result of changes in the so-called general circulation of the atmosphere.

This general circulation, with all its variations, diurnal, annual, and secular, is dependent upon the intrinsic density of each portion of the atmosphere and on numerous forces, such as the heat received from the sun, the attraction of the sun, moon, and earth, the resistance offered by the irregular surface or the earth, and the interaction of slow and rapidly moving masses of air. The proper study of this subject constitutes the application of hydrodynamics to meteorology.

The meteorological problem has some analogy to that offered by the hydraulics of the Mississippi River, where cut-offs, cave-ins, mud-banks, and crevasses are continually forming and re-forming. We do not expect to be able to foretell when and where these will occur many years in advance, but we do keep a watch on the condition of the river; and when conditions are favourable for the formation of any important change, we watch the process until the catastrophe becomes more or less imminent, and then begin to make estimates, that may be called predictions, as to the exact time and place of the event.

In meteorology the best we can do at present in long-range predictions is to chart and study the occurrence of abnormal weather conditions over the whole globe; these phenomena must be interpreted in the light of all the knowledge we have of the mechanics of the atmosphere, for they are the results of purely mechanical operations covering the whole range of the mechanics of heat, gases, and vapours.

SCIENTIFIC SERIAL.

The Quarterly Journal of Microscopical Science, November.—On Julinia, a new genus of compound ascidians from the Antarctic Ocean, by W. T. Calman (plates 1–3). The colony is described as irregularly cylindrical in shape, measuring 78·5 cm. in length, and from 1·5 to 2·5 cm. in diameter; it was found floating on the surface of the sea in the north of Erebus and Terror Gulf; a considerable quantity was seen; no attaching fibres were found, but it was probably an attached form. The species is described as *Julinia australis*, and it is provisionally placed in the Distomidæ.—Hermaphroditism in mollusca, by Dr. Paul Pelseneer (Ghent) (plates 4–6). Hermaphroditism is found in the Amphineura, the Gastropoda, and the Lamellibranchia. It is not self-sufficient, is sometimes protandric; it would seem to the author to be not a primitive arrangement, but to be derived from the unisexual state, and to have been established upon the female organism.—Description of the cerebral convolutions of the chimpanzee known as "Sally," with notes on the convolutions of the brains of other chimpanzees and of two orangs, by W. Blaxland Benham (plates 7–11).—On the inadequacy of the cellular theory of development and on the early development of nerves, particularly of the third nerve and of the sympathetic, in Elasmobranchii, by Adam Sedgwick, F.R.S. More than ten years ago the author called attention to the inadequacy of the cellular theory of development: "Embryonic development can no longer be looked upon as being essentially the formation by fission of a number of units from a single primitive unit, and the coordination and modification of these units into a harmonious whole. But it must rather be regarded as a multiplication of nuclei and a specialisation of tracts and vacuoles in a continuous mass of vacuolated protoplasm." And "although opinions have changed on this important subject, and although there are some who think that they have escaped from the domination of this fetish of their predecessors, yet as a matter of fact the cellular theory of development is still rampant, still blinds men's eyes to the most patent facts, and still obstructs the way of real progress in the knowledge of structure." When a student begins his zoology he is told that "the various structures present in a protozoon are all parts of one cell, whereas in a metazoon the various parts are composed of groups of cells which differ from one another in structure." When in a later period of his studies he begins embryology, "the importance and distinctness of the cell meets him at every step, from the complete cleavage which he is led to believe is primitive, to the development of nerves according to the views of His." If we take the so-called mesenchyme tissue of elasmobranch embryos, it is described as consisting of "branched cells lying between the ecto- and the endo-derm," while, as a matter of fact, "the separate cells have no existence," but "there is a reticulum of a pale non-staining substance holding nuclei at its nodes. And far from the development of nerves being an outgrowth of cell-processes from certain central cells, it is simply a differentiation of a substance which was already in position" This important memoir is so condensed as to make it extremely difficult to condense it further, but enough has been given to indicate its nature.—On *Benhamia cæcifera*, n. sp., from the Gold Coast, by W. B. Benham (plate 12). This large species (20 inches) was found at Axim in the Fantee country, on the west coast of Africa.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 22.—"A Determination of the Specific Heat of Water in terms of the International Electric Units." By Prof. Arthur Schuster, F.R.S., and William Gannon, Exhibition (1851) Scholar, Queen's College, Galway.

This research was originally undertaken by Prof. Schuster and Mr. H. Hadley, before the authors were aware that Mr. E. H. Griffiths was engaged on a similar investigation. After a number of preliminary experiments, and just as the final arrangements for the conduct of the measurements were being definitely made, Mr. Hadley, on his appointment to the head-mastership of the School of Science and Art, Kidderminster, had to leave Manchester.

On Mr. Hadley's departure, Mr. W. Gannon took his place. From the former gentleman we received a good deal of help in the devising and construction of some important parts of the apparatus.

The principle of the method we have used is extremely simple. The electrical work done in a conductor being measured by $\int ECdt$, where E is the difference of potential at the ends of the conductor, C the current, and t the time. We keep the electromotive force constant, and measure $\int Cdt$ directly by a silver voltameter. We do not, therefore, require to know the resistance of the wire, and we thus avoid the difficulty of having to estimate the excess of temperature of the wire over that of the water in which it is placed. We also gain the advantage of not having to measure time, and therefore to be able to complete the experiments more quickly than we could have safely done if the length of time the current passed had to be measured with great accuracy.

Our final value is

J = 4·1804 Joules on the mercury scale of hard French glass,
4·1905 on the nitrogen scale,
4·1917 on the hydrogen scale,
at a temperature of 19°·1.

In comparing our results with that of other observers, we have in the first place to consider the value which Mr. Griffiths has obtained in his very excellent series of measurements. His final result (*Roy. Soc. Proc.* vol. lv. p. 26; *Phil. Trans.* clxxxiv. A (1893) is

$$J = 4{\cdot}1982(1 - 0{\cdot}00266\,\overline{\theta - 15}) \times 10.^7$$

This refers to the nitrogen thermometer. At a temperature of 19°·1, the value would be reduced to 4·1936, which corresponds to our 4·1905 at the same temperature. Griffiths' value is to be increased slightly, owing to the fact that he really measures the difference between the specific heat of water and of air. This would increase the value of J by ·0011 about, so that the value of J at 19°·1 would be raised to $4{\cdot}1947 \times 10^7$, which is exactly one part in a thousand larger than ours. The difference is small, but must be due to some systematic error, as both Griffiths' value and our own agree so well with each other, that ordinary observational errors and accidental disturbances could not have produced so large a difference in our results. The least satisfactory part of a calometric measurement must always be the application of the cooling correction, and we have considered it of great importance to reduce that correction as much as possible. The uncertainty of the cooling correction does not necessarily depend on its value; thus we can much diminish it by starting, as we have done in the third series, with the initial temperature of the calorimeter about as much below that of the water jacket as the final temperature is above it; yet the *uncertainty* of the correction does not seem to us to be diminished by that process. We may reasonably estimate the uncertainty due to the cooling correction, by calculating what the error in the observed rate of cooling, either at the beginning or the end of the experiment, must have been in order to produce a difference of one part in a thousand in the final result. We find in our own experiments that the error must have amounted to more than 15 per cent. We consider it unlikely that so large an error occurred always in the same direction. Apart from the cooling correction, however, it is difficult to see how a difference one-tenth per cent. in our result can be produced unless by the accumulation of a number of small errors

The difference between our value of the equivalent and that of Mr. Griffiths are, however, of smaller importance than the difference which exists between them and the equivalent as determined directly by Joule, Rowland, and Miculescu. Joule's latest value, which is the only one which needs consideration, is 772·65 foot-pounds, at 61°·7 F. The number refers to the degree as measured by Joule's mercury thermometer. Rowland adds to this a correction to the air thermometer of about 3, and another small correction for a change in the heat capacity of the apparatus, which brings the value up to about 776. The correction to the air thermometer has been obtained by means of a comparison made by Joule himself with one of Rowland's thermometers. Joule's original thermometers have been temporarily placed by Mr. B. A. Joule in the hands of Prof. Schuster, in order that an accurate comparison may be instituted between them and modern thermometers. A full description of the comparisons made will be given on another occasion. The result arrived at shows that the correction is less than that assumed by Rowland, and would bring his value up only to 775 at the temperature indicated.

Great weight must be attached to Rowland's determination, which at the temperature to which Joule's number applies is 777·6, and at 19°·1, 776·1, corresponding to our 778·5.

Equivalent in foot-pounds at Greenwich at 19°·1 referred to the "Paris" Nitrogen Thermometer.

Joule.	Rowland.	Griffiths.	Schuster and Gannon.
774	776·1	779·1	778·5

We now turn to an investigation of Miculescu (*Annales de Chimie et de Physique*, vol. 27, 1892), in which the mechanical equivalent of heat is measured directly by what seems a very excellently devised series of experiments. Its result is $4{\cdot}1857 \times 10^7$.

In order to compare Miculescu's value with that of others, we must apply a temperature correction which is somewhat doubtful; but taking the mean of Rowland's and Griffiths' values as the most probable at present, we obtain at 15° the following table:—

Equivalent in foot-pounds at Greenwich at 15° referred to the "Paris" Nitrogen Thermometer.

Joule.	Rowland.	Miculescu.	Griffiths.	Schuster and Gannon.
775	778·3	776·6	780·2	779·7

If we remember that Rowland's number referred to the "Paris" nitrogen thermometer would probably be smaller by one unit, we are struck with the fair agreement there is, on the one hand, between the results of Joule, Rowland, and Miculescu, and on the other hand between Griffiths and ourselves.

As far as we can draw any conclusions from the comparison, it seems to point to a difference in the value obtained by the electrical and direct methods. Whether this difference is due to some remaining error in the electrical units, or to some undiscovered flaw in the method adopted by Mr. Griffiths and ourselves, remains to be decided by further investigation.

Linnean Society, December 6.—Mr. C. B. Clarke, F.R.S., President, in the chair.—Mr. E. M. Holmes exhibited and made remarks upon a small collection of Japanese marine algæ, some of which were of considerable rarity in European collections.—Prof. D. Campbell brought forward some illustrations of the relations of vascular cryptogams, as deduced from their development. His remarks, which were listened to with great attention, gave rise to an interesting discussion, in which Prof. Bower, Dr. D. H. Scott, Mr. Carruthers, and Prof. Marshall Ward took part.—"A new revision of the *Dipterocarpeæ*," was the title of a paper by Sir Dietrich Brandis, K.C.I.E., who gave an excellent account of this order of forest trees, their structure and mode of growth, together with a survey of the literature relating to them, and a clear exposition of his views concerning classification. He pointed out that the order *Dipterocarpeæ* consists almost entirely of large trees which do not flower until they have attained a great size, with a spreading crown on a branchless stem often more than 100 feet high. Hence it is difficult to obtain complete specimens in flower and fruit; and this explains why a large proportion of the genera and species have only of late years become accurately known. Korthals in 1840 knew 34 species; A. de Candolle in 1868 described 126; Mr. Thiselton Dyer in 1874 estimated the order at 170. Sir D. Brandis now considers that there are 320 well-ascertained species, belonging to sixteen genera, omitting the genera *Ancistrocladus* and *Lophira*, which he regards as justly excluded from the order. Notable species are the Sâl tree of India (*Shorea robusta*), great forests of which extend along the foot of the Himalayas and in Central India, the Eng tree (*Dipterocarpus tuberculatus*) of similar growth in Burma, and others found in Cochin China and Borneo. In the discussion which followed, an extended criticism was offered by Mr. Thiselton Dyer, who had paid special attention to this order of trees, and who, admitting the soundness of the author's views, considered his exposition of them most valuable. The paper was illustrated by lantern-slides showing the chief peculiarities of structure in the flowers and fruit.

Royal Meteorological Society, December 19.—Mr. R. Inwards, President, in the chair.—Mr. H. Southall read a paper on floods in the West Midlands, in which he gave an interesting account of the great floods which have occurred in the rivers Severn, Wye, Usk, and Avon. He has collected a valuable record of the floods on the Wye at Ross, which he arranges in three classes, viz. (1) primary or highest of all, those of 14 feet 6 inches and above; (2) secondary, those with a height of 12 to 14½ feet; and (3) tertiary, those with a height of 10 to 12 feet. The dates of the floods above 14 feet 6 inches are as follows: 1770, November 16 and 18; 1795, February 11 and 12; 1809, January 27; 1824, November 24; 1831, February 10; 1852, February 8 and November 12. The height of the recent flood on November 15, 1894, was 14 feet 3 inches, which was higher than any flood since November 1852. The flood on the Avon at Bath on November 15, 1894, is believed to have been the highest on record.—Mr. R. H. Scott, F.R.S., gave an account of the proceedings of the International Meteorological Committee at Upsala in August last, with special reference to their recommendations on the classification of clouds and the issue of a cloud atlas (see NATURE, December 20).—A paper by Mr. S. C. Knott was also read, giving the results of meteorological observations made at Mojanga, Madagascar, during 1892 to 1894.

EDINBURGH.

Royal Society, November 27.—Prof. Copeland, Astronomer-Royal for Scotland, Vice-President, in the chair.—Prof. M'Kendrick read a paper on observations with the phonograph, with experimental illustrations. He has devoted great attention to the development of the instrument. He uses very large conical metallic resonators, and has succeeded largely in getting rid of the nasal sound of the instrument, so that part-songs and concerted instrumental pieces can be reproduced with considerable accuracy, and can be made audible throughout a very large room. He exhibited, by means of a lantern, a large number of photographs of the surface of the wax drum, pointing out the peculiarities of the record corresponding to various qualities of instrumental or vocal notes and chords.

December 3.—Prof. Geikie, Vice-President, in the chair.—Dr. John Smith communicated notes on a peculiarity in the form of the mammalian tooth. Roughly speaking, the general appearance of the mammalian tooth is that of a cone, flattened to some extent, and twisted about its axis to a greater or less degree, and then bent so as to form a portion of a circle. If this bending takes place to a large extent, it is not easy to recognise the axial twist. The author showed that the characteristic is always present, being easily seen in the strong spiral of the narwhal's tusk, or the remarkably twisted teeth of the *Mesoplodon* described by Sir William Turner in the Reports of the *Challenger* expedition, and being almost unrecognisable in the human tooth. The axis of the twist is directed backwards and inwards from the face of the tooth, and it is this characteristic which enables dentists to distinguish teeth from each side of the mouth.—Mr. Gregg Wilson read a paper on the development of the Müllerian duct of amphibians. He contends that this duct does not arise from splitting of the segmental duct, but is developed in the same way as the Müllerian duct of the higher mammals.—Dr. George Hay, Pittsburg, submitted an account of a new method of correcting courses at sea. His apparatus consists of two superposed compass cards, whose north points are set at an angular distance apart which is equal to the magnetic variation. The true course being read off on one, the corresponding point of the other gives the compass course. Simple as this arrangement is, Dr. Hay asserts that he has never known it to be employed at sea.—Prof. Tait read a note on the constitution of volatile liquids. His equation, deduced from the graph of the *Challenger* results, applies with great accuracy to non-volatile liquids, such as water, at ordinary temperatures and at pressures up to 3000 atmospheres. It does not apply with quite so great accuracy at the lower pressures to such liquids at or near their boiling points, and it is still less accurate in this respect when applied to volatile liquids. Prof. Tait suggests that this may be due to the existence, in the liquid, of dissolved gases or of vapour.—Prof. Tait also read a note on the isothermals of ethylene." His equation enables one to calculate, with great accuracy, the pressure, at a given temperature and volume, in the neighbourhood of the critical point, from Amagat's observations; but the volume, at a temperature and pressure in the neighbourhood of the critical point, given by Amagat's observations, cannot be calculated, with any approach to accuracy, from the equation. This is due to the excessive rapidity with which the difference of the volumes in the liquid and vapourous states diminishes with increase of temperature as the critical point is approximated to.

PARIS.

Academy of Sciences, December 17.—Annual public meeting.—M. Maurice Lœwy in the chair.—The proceedings were commenced by an address, delivered by the President. The past year was referred to as a period of slow growth and consolidation of knowledge rather than as being characterised by any very brilliant discoveries. The members and associates deceased during the year—MM. Edmond Fremy, Brown-Séquard, Mallard, Duchartre, Ferdinand de Lesseps, General Favé, MM. Hermann von Helmholtz and P. Tcéhbichef—were referred to appreciatively, and their influence on the progress of science pointed out. The system of prizes given by the Academy was referred to at the conclusion of the address, which was followed by the reading of the awards by M. Berthelot. In Geometry the grand prize for the mathematical sciences was awarded to Dr. Julius Weingarten; honourable mention was accorded to M. C. Guichard. The Bordin prize was adjudged to M. Paul Painlevé (Analytical Mechanics), MM. Liouville and Elliot receiving honourable mention. The Francœur prize was obtained by M. J. Collet; the Poncelet prize by M. H. Laurent, for his mathematical works. In Mechanics the extraordinary prize of 6000 francs was awarded to (1) M. Lebbond (2000 fr.), for his works on electricity; (2) Commandant Gossot (2000 fr.), for the determination of the velocity of projectiles by means of sound phenomena; (3) Commandant Jacob (1500 fr.), for his study of the ballistic effects of the new powders; (4) M. Souillagouët (500 fr.), for his "Recueil de Tables du point auxiliaire." The Montyon prize fell to M. Bertrand de Fontvioland, for his works on the resistance of materials. The Plumey prize was equally divided between M. André Le Chatelier and M. J. Auscher. M. Autonne received the Dalmont prize (3000 fr. triennially) for his works on analysis. In connection with the same prize, M. Maurice d'Ocagne was awarded a supplementary prize, M. Pochet exceptionally honourable mention, and M. Willotte very honourable mention. In Astronomy the Lalande prize was adjudged to M. Javelle for his researches on nebulæ. The Damoisean prize, for perfecting methods of calculation of perturbations of minor planets, went to M. Brendel. The Valz prize was awarded to M. Coniel for work on small planets, and the Janssen prize to Prof. George Hale (solar photographic observations). In Statistics the Montyon prize was adjudged to M. Boutin, a supplementary prize to Dr. Faidherbe, and honourable mention to Dr. A. Cartier and Dr. Tastière. In Chemistry the Jecker prize was divided between MM. Barbier, Chabrié, P. Adam, and Meslans. In Mineralogy and Geology the Vaillant prize was not awarded, as no memoir had been presented. In Botany the judges for the Desmazières prize awarded an "encouragement," to M. Sappin-Trouffy. The Montagne prize was accorded to M. Husnot for his publication on Mosses; Brother Joseph Héribaud received a second prize for his "Diatomaceæ of Auvergne." In Anatomy and Zoology the Thore prize to M. Cuénot for work on the physiology of insects. The Savigny prize to M. Mayer-Eymar for researches in conchology. The Da Gama Machado prize was reserved, although the Commission gave high praise to work submitted by Dr. L. Phisalix and M. L. Joubin. In Medicine and Surgery the Montyon prize to (1) M. Félizet for a treatise on "inguinal hernia of infancy, (2) M. Laborde for his work on "the physiological treatment of the dead body," (3) M. Panas for his treatise on "affections of the eyes." Mentions and minor awards went to MM. Legendre, Broca, Vacquez, Vaudremer, Marcel Baudouin, Ferreira, Ernest Martin, Pietra Santa, Voisin, and Petit. The Barbier prize was awarded to Prof. Henri Leloir for his work on scrofulo-tuberculosis, Drs. Artault and Tscherning receiving honourable mention. The Bréant prize was adjudged to M. Arloing for his work on the bacillus of peripneumonia in cattle; the Godard prize was accorded to MM. Melville-Wassermann and Noël Hallé; the Parkin prize to MM. Behal and Choay; the Bellion prize between Dr. Lardier and MM. Beni-Barde and Materne, Dr. Renon receiving honourable mention; the Mége prize to M. Faure; the Lallemand prize to M. Gley, honourable mention to MM. Nabias and P. Janet.—In Physiology, the Montyon was divided between MM. Phisalix and Bertrand and M. Raphaël Dubois, honourable mention being given to MM. Morot, Blanc, and Philippon; the Pourat prize fell to M. Haufmann, a mention being accorded to M. Thiroloix. In Physical Geography, the Gay prize was awarded to M. Martel. General prizes—The Montyon prize (unhealthy industries) was divided between MM. Balland and Lavet; the Cuvier prize was awarded to Mr. John Murray of the *Challenger* expedition; the Trémont prize was accorded to M. Émile Rivière; the Gegner prize to M. Paul Serret; the Delalande-Guérineau prize to the Marquis de Folin; the Jérome Ponti prize to Commandant Defforges; the Tchihatchef prize to M. Pavie; the Houllevigue prize to M. Bigourdan; the Cahours prize (1) to M. Varet and (2) M. Freundler; the Saintour prize to MM. L Deburaux and M. Dibos; the Laplace prize to M. Édouard Glasser; and the Rivot prize to MM. Glasser, Leprince-Ringuet, Henri Parent, and Le Gavrian. The programme of prizes for 1895, 1896, 1897, and 1898 is given in detail so far as yet decided.

BERLIN.

Physiological Society, November 23.—Prof. du Bois Reymond, President, in the chair.—Prof. Zuntz gave an account of his researches on the measurement of the amount of blood in circulation and the work done by the heart. For the horse he found 71 to 72 c.c. of blood per kilo body-weight per second; for the dog, as based on the consumption of oxygen, 78 c.c. These values do not correspond to the marked difference in size of the animals, but may be explained as due to the fact that the dog was experimented upon while fasting and at rest, whereas the horse was not. For a horse in complete rest the value obtained was 50 c.c. For man he estimated the value at 60 c.c. Blood-pressure falls but slightly along the arterial system, and was found to be nearly the same in the carotid and in a small branch of the facial artery. The work done by the human heart he calculated as amounting to about 20,000 kilogram-metres in the twenty-four hours. When the body is working the work done by the heart increases also, so that in the case of the horse the blood pumped out now amounted to 600 c.c. per kilo per second, or twelve times as much as during rest. The frequency of the pulse could by work be increased four-fold, and the work done by the heart to thrice its normal amount.—Dr. Cohnstein had carried out further experiments on the transudation of solutions of salts into distilled water, and using mixtures of salts as well as mixtures of colloids and crystalloids, he had observed that an increased transudation of the solids follows upon an increase of external pressure. He applied these results to explain the mode of formation of lymph, which he attributed to transudation as well as to filtration, thus opposing Heidenhain's view that it is due to a distinct secretion. He explained the action of lymphagogues, on the basis of his own experiments, as due to the power these substances possess, when mixed with an albuminous fluid, of confining the diffusion of the external fluid entirely towards the interior of the tube which contains them in solution.

AMSTERDAM.

Academy of Sciences, November 24.—Prof. Van de Sande Bakhuyzen in the chair.—Prof. J. A. C. Oudemans communicated the results obtained in solving two problems, an astronomical and a geodetical one, namely:—(1) In how long a period do stars, the velocities of which in the line of vision are known, lose or gain 0·1 magnitude? (See "Our Astronomical Column," December 13, p. 160).—Dr. Van Romburgh (Buitenzorg) has examined the essential oils of *Polygala variabilis*, H. B. K., *B. albiflora*, *Polygala oleifera*, Heckel, and *Polygala Javana*, and found them to be nearly all methylsalicylate.—Mr. Jan de Vries: on a group of plane curves. This paper contains some theorems on plane curves ϕ of the $(n + m)^{th}$ order, with m^2 double points, (Δ), forming the base of a pencil of curves of the m^{th} degree.

BIOLOGICAL LECTURES AND ADDRESSES.

Biological Lectures and Addresses delivered by the late Arthur Milnes Marshall, M.A., M.D, D.Sc., F.R.S. Edited by C. F. Marshall, M.D., B.Sc., F.R.C.S. (London: Nutt, 1894.)

MANY of us remember the pleasure experienced in listening to the vigorous addresses of Prof. Milnes Marshall, whose sudden death, about a year ago, was such a blow to biologists and to all interested in the spread of scientific education. In reading them now, the energy and humour of the speaker are ever present in the memory, giving life to the apt illustrations and clearly expressed thoughts.

The choice of appropriate subjects for the occasion of these addresses shows remarkable discrimination. It is quite clear that the late Prof. Milnes Marshall believed that a single address—if heard at the right point in his career, and delivered with the confidence of this belief—might change the whole attitude of mind with which a student approached his subject.

Lecturing to the Owens College Medical Students' Debating Society, he chose as his subject "Embryology as an aid to Anatomy." In preparing to address a class of students expected to deal with, and to remember, in the course of their daily work, innumerable details which are as yet far from receiving a scientific interpretation, he selected embryology, which "offers an explanation of many otherwise completely unintelligible anatomical facts"; and by the example of the development of the nerves supplying the muscles of the eye, the thoughts of many young anatomists may well have been turned into a direction which was of the most inestimable benefit to their study.

Equal wisdom and foresight were shown in the selection of subjects for addresses to the Members of the Manchester Microscopical Society, viz. "Inheritance" (1888), "The Shapes and Sizes of Animals" (1889), "Some Recent Developments of the Cell Theory" (1890), and "Death" (1893). In the choice of these subjects, and in their treatment, the Members of the Society are shown that the most profound biological problems are to be approached and, perhaps, solved by the study of the most minute detail and the lowest forms of life. The student thus made fully aware of the dignity and possibilities of his subject, will not be likely to forget, in the patient investigation of histological or biological detail, the wide issues which are at stake.

The subjects chosen for presentation to other audiences are just as happy. Sometimes, as in "The Theory of Change of Function," a difficulty in evolution by natural selection is taken as the subject, and the final solution given in the clearest and simplest manner. It would be well if this address were widely known, for the difficulty it deals with is still frequently raised, just as if no explanation had ever been forthcoming. In other cases, wide questions, such as "The Influence of Environment" or "Animal Pedigrees," form the subjects of the addresses.

The addresses abound in humorous and apt illustrations. Thus, on p. 39, in order "to show that, even in our worldly transactions, changes of environment often produce not only direct and immediate changes and re-adjustments, but also definite and calculable ones," he gives as an example the following:—"Let *a* be a merchant, and *b* his purse: the combination *ab* will at once strike you as a natural and stable one. . . . Now let *c* be a highwayman, and *d* his pistol: the combination *cd* is again recognised as a natural and stable one. Now, bring the compound *ab* into the presence of the compound *cd*, and mark how the stability of the former is shaken. . . . The several elements become rearranged in a manner that finds perfect expression in the formula—

$$ab + cd = a + bcd."$$

Again, in order to illustrate the tendency towards reversion to an ancestral condition, the card house is selected—

"The resulting structure is a far more imposing one than the pack of cards when laid flat on the table, but it is also an eminently unstable one, its instability being directly proportional to the extent to which it departs from its initial condition." (p. 104.)

"The influence of food yolk on development" is compared to "that of capital in human undertakings" (p. 224), the metaphor being worked out in an interesting and amusing manner. Prof. Weismann's views on the absence of death in Protozoa are illustrated on p. 273 as follows:—

"If the original Amœba be called Tom, and the products of fission Dick and Harry, the upshot of the process may be expressed by saying that Tom has disappeared without having died, while Dick and Harry have come into existence without having been born. Nothing has died, there is no corpse to bury, and our ordinary ideas with regard to individuality and identity fail altogether to afford answer to the question—Where is Tom at the end of the process?"

There are a few sentences in the addresses which are perhaps capable of misconstruction. Prof. Milnes Marshall appears to have hesitated to accept the belief in the hereditary transmission of acquired characters, and yet there are some statements which seem to imply this belief. This is the case with the statements that the white man and the negro have been evolved "through the long-continued action of selection and environment" (pp. 247 and 358), that modifications of development have occurred "due chiefly to mechanical causes" (p. 316), that the "larger size of the eggs of fresh-water forms appears to be dependent on the nature of the environment" (p. 313), although in this case it is clearly shown on the following page that environment is believed to act selectively and not directly.

The term "acquired character" is made to bear still further burdens in the way of special interpretations. It was unfortunate so late as 1890 to continue to speak of the distinction in development "between those characters which are really historical and inherited, and those which are *acquired* or spurious additions to the record" (p. 307), or to speak of the view that Amphioxus and the Cyclostomes are "degenerate animals—whose simplicity is *acquired* and deceptive rather than real and ancestral." (p. 335.)

The book is well and clearly printed, and has been extremely well edited. The only printer's error noted was in the title of Mr. Oldfield Thomas' paper on p. 318.

E. B. P.

TEXT-BOOK OF AGRICULTURE.

Advanced Agriculture. By H. J. Webb, Ph.D., B.Sc. (Lond.). 8vo., pp. vi. and 672. (London: Longmans, Green, and Co., 1894.)

TEXT-BOOKS of agriculture are rapidly increasing in number. The name of the author on the title-page of this is that of the late Principal of the Agricultural College at Aspatria, Cumberland, who, most unfortunately, was unable to complete the work. He was struck down at a comparatively early age, and in the midst of hard work and a successful career. He is most highly spoken of, and deservedly so, in the preface by the editor of the book, Mr. J. Lister, of Aspatria. From such hands we anticipated much and good work, though the task might appear heavy. We regret to say that we have been greatly disappointed.

We are told that—

"This work, though primarily intended for the advanced stage of the Science and Art Departments' Examination in Principles of Agriculture, will also cover the greater part of the syllabus of the Honours stage. Care has, however, been taken not to adhere too rigidly to the syllabus in question, and we trust it may be found equally serviceable for the examination for the diploma in Agriculture of the Highland and Agricultural Society in Scotland, and the senior examination of the Royal Agricultural Society of England."

Even the fact that the book has been prepared mainly to assist students to pass examinations, can hardly excuse some of the statements we meet with. In agricultural geology we are told, among other scraps of information that zeolites are "hydrated silicates of alumina or lime." This is scarcely true. "Diorite consists of plagioclase and hornblende." This is true, but as the meaning of plagioclase is nowhere explained, it does not help the student much. In agricultural physics we learn that "a heavy soil might contain absolutely double the amount of phosphoric that a light soil did, although it would show only the same percentage if it were twice as heavy." We have tried to believe this, but till now we do not understand it. In engineering, a definition of horse-power is given without any mention or suggestion of *time* as a possible factor.

In chemistry, Rendonda [Redonda] and Alta Vela phosphates are said to contain a large quantity of *alum;* leather to contain 4½ to 9 per cent. of *ammonia*, and meat-meal and meat-guano to contain much *ammonia*. This is the more confusing, as in other manures, mentioned on the same page, the percentage of *nitrogen* is correctly given; but this confusion of ammonia with the ammonia equivalent of the contained nitrogen is common throughout. Ammonium chloride is said to contain about 18½ per cent. of water and 32½ per cent. of ammonia. The formula of monocalcic phosphate is correctly given as $CaH_4P_2O_8$, and tricalcic phosphate as $Ca_3P_2O_8$, and, yet, in one analysis 18·01 per cent. of the former is said to be equal to 28·1 per cent. of the latter, and in another case 19·2 per cent. of monocalcic phosphate is said to be equal to 30·07 per cent. of tricalcic phosphate made soluble: of course the so-called monocalcic phosphate in these analyses is calcium metaphosphate, formerly known as "biphosphate"; but how can the student know this? Cellulose is described as a white amorphous powder.

In agricultural botany, we are told that "protoplasm generally presents itself as a granular semi-fluid substance with or without a cell-wall." "The corolla, when present, usually consists of green leaves or sepals, sometimes scarcely noticeable." This later statement is, of course, only a misprint; but it is also only an example of several similar serious misprints.

The root residues of crops remaining in the soil are said to "consist very largely of protoplasm." The section on farm crops, however, in which this occurs, is written in a curious style, somewhat difficult to follow.

On looking up information regarding anthrax, we find that "although a disease of the blood, the writer [in this case Mr. H. Thompson] considers it more of a dietetic nature, having seen it produced from steeped brewers' grains allowed to stand till they had reached the acetous stage of fermentation. It is also produced by the bay bacillus, obtained from the fermentation of chopped hay and from mouldy cotton-cakes, more particularly the undecorticated variety. He has also seen it arise in certain undrained lands. Although very fatal to other animals, such as dogs, cats, and poultry, that may have eaten the flesh or blood, yet he considers it neither infectious nor contagious, having never known it to extend beyond the buildings in which it originated. Again, the disease was always traceable to some peculiarity of the feeding, and the writer thinks that it is analogous to an aggravated form of *red water*." And this stuff is set forth as *advanced* agriculture. There are several very startling statements in the chapter on veterinary science; *e.g.* in retention of the fœtus, "different bones belonging to the fœtus, such as jaw, scapula, ribs, humerus, and several others, are passed at times through the rectum."

In the chapter on agricultural entomology, we hardly suppose the author is serious when he recommends the use of rape-cake, at the rate of two or three tons per acre, to clear the field of wire-worms.

In part ii. of the book the misstatements are perhaps not quite so numerous or so serious, but they are not absent. In the chapter on permanent pastures, after a notice of the power which leguminous plants, with the aid of the low organisms present in the nodules on their roots, possess of appropriating free nitrogen, we are told that "this fact of the nitrogen-storing power of the leguminous plants explains the action of heavy dressings of nitrogenous manures on permanent pastures encouraging the growth of grasses, especially the coarser ones, at the expense of the clovers." We fancy that this *explanation* of the fact will not satisfy many readers.

The work of Rothamsted is frequently referred to and fully appreciated; but why should Rothamsted be spelt in three different ways in the book? Probably, however, every would-be advanced agriculturist knows that there are not three Rothamsteds.

But we have given enough instances of what are very serious flaws in the book. Much of the matter is exceedingly good and useful; but does not this really add to the danger of the work in the hands of the learner who is not in a position to sift the wheat from the chaff and the weeds?

We do not think that this book will serve to advance the reputation of its author, nor to advance agriculture. We submit that "advanced agriculture" is not agriculture *plus* a smattering of chemistry, a dip into geology, a pinch of botany, a skim of entomology, a sniff at meteorology, and so on; even if the sciences be correctly expounded. The text-book of agriculture, like that of other subjects, has no doubt to pass through stages of evolution, and we trust it will not long remain at the stage indicated by this book.

EWING ON THE STEAM ENGINE.

The Steam Engine and other Heat Engines. By Prof. J. A. Ewing, M.A., B.Sc., F.R.S., M.Inst.C.E. (Cambridge: The University Press, 1894.)

ENGINEERING students and others will welcome the present volume as one likely to increase their knowledge of an important branch of engineering, from the pen of an acknowledged master of the science; any work by Prof. Ewing is sure to be read by engineers generally, and treated as a book for constant reference.

As is well known, Prof. Ewing wrote some valuable articles for the "Encyclopædia Britannica" on this subject, and it is an expansion of these articles which constitutes the basis of this work. As a University text-book this volume will fill a great want, treating as it does, from the theoretical side, a subject only descriptively dealt with in the majority of such text-books. As the author remarks: "The endeavour throughout has been to make evident the bearing of theory on practical issues."

The first six chapters may be said to contain the early history of the steam engine, and a scientific treatment of the general behaviour of steam in the cylinder, as well as the general theory of heat engines. The information thus brought together is of a valuable nature, and the references which are made, add considerably to the usefulness of the work. To the thoughtful practical engineer, this portion of the book will form a perfect mine of matter for careful consideration.

The testing of steam engines has of late years become a common occurrence, thanks to Profs. Kennedy, Osborne Reynolds, and many others. Designers and manufacturers of such engines have everything to gain by such experiments; few being, like the late Mr. Willans, capable of carrying out scientifically accurate trials of their own engines. Chapter vi. deals with this important question. Many useful hints are given, and sources of error carefully pointed out. As indicator diagrams play such an important part in the trials of steam engines, it is interesting to note that the Crosby Company's modified form of Richards' Indicator is considered by Prof. Ewing to be one of the best.

Compound expansion comes in for very full and accurate treatment; many sets of indicator diagrams are explained and illustrated, and the difficult matter involved in the combination of such diagrams is lucidly dealt with. Of the advantages of compound expansion in the use of high-pressure steam, we are told much, and also of the mechanical advantages of such an arrangement. We cannot help pointing out that, in this matter, the practical men on the Clyde were singing the praises of compound engines before the theoretical men would admit of their utility or economy. On valves and valve gears our author has much to say, although we notice nothing remarkable in the chapter. Locomotive engineers do not trust entirely to the drawing-board or calculation in the design of valve gears. It is now the practice to try the proposed gear as a full-size model on the valve gear testing machine, and so to obtain the best results. The latest machine of this kind has been erected in the drawing-office of Messrs. Sharp, Stewart, and Co., the eminent locomotive engineers, of Glasgow. The saving of time is great, and very accurate results are obtained. In fact, in such drawing-offices, the old valve diagrams, with their many curves, are things of the past, and a simple table of leads, cut-offs, suppressions, &c., for the different degrees of expansions, has taken their places.

Chapter ix. treats of the many forms of governors used for regulating the work done in the steam engine, commencing with Watt's simple arrangement, and finishing with the differential or dynamometric governors invented by the late Sir W. Siemens; and further on in the book we find much useful information concerning the work on the crank shaft. Diagrams of crank efforts are given, and the effect of friction and of the inertia of the reciprocating pieces are duly discussed. The balancing of machinery is an all-important subject, in fact the life of any machine depends upon the balancing of its moving parts; for this reason, we are sorry to see that Prof. Ewing has so little to say on this subject generally, and particularly on the balancing of locomotives. If theory is of any help to the locomotive engineer at all, surely it could be best applied in balancing; some engineers balance the whole reciprocating weight, others none; the majority about 30 per cent.: which is right? Prof. Ewing does not help us, but observes that "the final adjustment of the balancing masses is usually a matter of experiment, the locomotive being hung in chains to allow its oscillation to be observed"; this, to say the least of it, is never done in this or any other country.

The production of steam is the subject treated in the following chapter; the illustrations of the different boilers, with the descriptions, are excellent. The only specimens of water-tube boilers illustrated are the Thornycroft and the Babcock and Wilcox, the latter used principally for stationary engines. The Thornycroft boiler is the forerunner of similar types; for instance, the Yarrow and the Clyde among others, all of which are considerably lighter than the ordinary marine boiler. As an example of the locomotive boiler, one of the London and North-Western Railway Company is taken as typical of British practice. As an example of an injector for feeding boilers, an old-fashioned type of Giffard injector is illustrated, but more recent types are described. Mechanical stoking and the use of liquid fuel are also mentioned.

The following chapters conclude the work, occupying some sixty pages with descriptions of forms of steam engines, air, gas, and oil engines. The Willan's central valve engine is well illustrated, and the description does credit to what is probably the most economical steam engine ever designed. A description is given of rotary engines, but none are illustrated. The "Rota" engine, designed and made by MacEwan Ross, of Glasgow, might have been included with advantage. The locomotive is outlined, and the compound type described; but no information as to tests is given, probably because no trustworthy data can be obtained; and as no British Railway Company, with one possible exception, is likely to build any more compound engines, it seems probable they are not the unqualified success they were originally claimed to be, although the Vauclain system, with four outside cylinders, appears to be a success in the States. But it must not be forgotten that the American rival is a very uneconomical engine when compared with our own.

N. J. L.

OUR BOOK SHELF.

Das Verhältniss der Philosophie zu der empirischen Wissenschaft von der Natur. By David Wetterhan. (Leipzig: W. Engelmann, 1894.)

THIS is the essay which gained the prize of 1000 marks offered, in 1891, by the Philosophical Society of Berlin. It consists of 110 pp., of which about twenty are occupied by notes and abstracts from various writers, in small print.

Naturally, in giving forth his own views, some of which possess considerable originality, the author makes continual and extensive use of the theories of Kant, Schopenhauer, Wundt, Bunge, and others; and one noticeable feature about the work is the full share of recognition accorded to English philosophers and scientists, such as Faraday, Herbert Spencer, Darwin, Romanes, and Huxley. The writer well remarks that the limits of scientific knowledge are everywhere and nowhere.

In the earlier pages the author discusses the relation between the physical and the psychical sides of nature. The theory of the conservation of energy has nothing to do with mental processes: it governs the quantitative relations of all processes of nature, but does not explain their qualitative differences. Sensation, consciousness, motor impulse, are not forms of energy, and do not correspond to them, but to the causes of qualitative changes in forms of energy.

The world of psychics cannot be separated from that of physics, and we must look forward to the future progress in the latter science to bring the qualitative changes into connection with the theory of the conservation of energy. The author shows by a very simple example—"Shall I kill that spider, or leave it alone?"—the effect of his will on surrounding nature; and the divergent effects thereon which would result from each of the wo alternative modes of procedure.

Memory he believes to be caused by an impulse of a certain kind, producing in the particular arrangement of the smallest particles in the ganglion cells and nerve fibres a modification in the same direction as was produced by the original impulse, and resulting in corresponding physical phenomena. But he acknowledges that, at present, we cannot explain "brain oscillations."

The principle of evolution sheds a light upon the psycho-physical problem: physical development is not the cause but the effect of psychical development, and the modifications in the brain and nervous system throughout the animal kingdom are intelligible as resulting from psychical causes, whereas the physical causes, if they exist, remain hidden. He considers that even in palæontology we can detect traces of this psycho-physical process by the examination and comparison of the cranial capacity of the skulls of extinct reptiles and mammals. As man is the culminating point in mental development amongst mammals, so is the ant amongst insects; but clearly this position has in each case been attained independently, and is independent of the structure of the nervous system. The inheritance of acquired characters is discussed, and the old difficulties presented by a disbelief in it are once more brought forward; and especially the difficulty in the adaptation of terrestrial mammals to a life in water, such as must have occurred in the ancestors of the Cetacea. The author endeavours to show that the principle of progressive psycho-physical development may admit of a vital-mechanical explanation, if the transference of acquired characters, as a consequence of changed functions, is possible for "keimplasma."

The author is apparently a practical man of science, and not a mere arm-chair philosopher; he fully recognises that philosophy must be based upon scientific experiments, and quotes Huxley's words, "The Laboratory is the forecourt of the temple of Philosophy."

Meteorology, Practical and Applied. By John William Moore, B.A., M.D., M.Ch., F.R.C.P.I. (London: F. I. Rebman, 1894.)

IT is to be hoped that this little book may meet with the popularity it deserves. Well written and well illustrated, it ought to recommend itself to that numerous class of whom some knowledge of meteorology is now required. The author, a medical practitioner, has evidently, first of all, but by no means exclusively, sought to interest medical officers of health and those who seek a qualification in preventive medicine and its allied branches. Writing for such students, the author has prudently not burdened his work with technical terms, or attempted to discuss with any completeness the general motions of the atmosphere depending upon the application of thermodynamics. Neither does he fall entirely into the popular and pleasing style of writing; though he does seek legitimate interest by exhibiting the many points in which meteorological inquiry bears on social and sanitary science, how it may benefit the agriculturist, protect the traveller, or instruct the physician.

The book is divided into four sections. In the first we find a very full and, considering the source from which it is drawn, probably accurate account of the history and development of the United States Weather Bureau It seems to have occurred to the author, that if he shows to the reader at an early stage the interest and devotion which the shrewd American gives to this subject, he will convince him that there is something in meteorology after all, beyond the dreary and wearisome accumulation of barometer and thermometer readings. Then we have, of course, the description of the necessary instruments in use, with their corrections. We are glad to see in this section due prominence given to Mr. Aitken's interesting work on atmospheric dust; and in the chapter on evaporation we notice that Mr. Apjohn's formulæ are given correctly, which is not the case in some other well-known elementary works. The third section of the book treats of climate and weather, a section that might with advantage have been made fuller; but in reviewing the whole subject of meteorology within moderate compass, it is necessary to curtail somewhere. The last section considers the influence of season and weather on disease. Here the author is apparently on very familiar ground, and the small space devoted to this topic is full of interest and suggestion. There are one or two slips in the text, as, for instance, on page 10, where the oft-repeated error is once again seen, of mistaking the axis of rotation of the earth for the plane of the equator; but such oversights are easily excused in presence of the collection of a large number of facts, well arranged and tersely expressed. W. E. P.

The Province of South Australia. By J. D. Woods, J.P. With a Sketch of the Northern Territory, by H. D. Wilson. Pp. 446. (Adelaide: C. E. Bristow, 1894.)

THIS account of the province of South Australia, from its discovery to the end of 1892 was, the preface informs us, written under the authority of the Government of the Colony. It may therefore be taken as an authoritative work of quite a different and a better kind than the many descriptions of Australia that have appeared during the past few years. The physical features, fauna, flora, climate and meteorology are fully described, and the story of the explorations of the interior of the continent is full of interest. There is a chapter on the agriculture of South Australia, and one on the minerals in which the province is so wonderfully rich. Those familiar with the history of education in South Australia will remember that prior to 1874 the colony did not possess a university. It was in 1872 that an endowment of £20,000, given by Sir W. W. Hughes, was applied to the founding of two professorships—one for classics and comparative philology and literature, and the second for English language and literature and mental and moral philosophy. Science was benefited shortly afterwards by a like donation from Sir Thomas Elder, to found a professorship for mathematics and another of natural science. The same benefactor gave £10,000 for the establishment of a medical chair in 1883, and £1000 for evening classes; and the Hon. J. H. Angas gave £6000 for the creation of a chair of chemistry, and £4000 for the establishment of scholarships and exhibitions. Though the Adelaide University was incorporated in 1874, the present University buildings were not opened until 1882. The School of Mines and Industries, as it is officially designated, was opened in 1889, and has steadily increased in influence and usefulness since then.

The chapter on the aborigines of South Australia is perhaps the best in the book, and as the author has had more than forty years' experience with the blacks, he writes upon what he is well qualified to describe. Altogether the volume includes much that has not hitherto appeared in print in a collected form, and therefore deserves to rank with the best books on Australia, its people, and its resources.

Measurement Conversion Diagrams. By Robert H. Smith, Professor of Engineering, Mason College, Birmingham. (London: Charles Griffin and Co., Limited, 1895.)

THE scope of this work is described on the title-page as follows:—"Forty-three graphic tables or diagrams for the conversion of measurements of different units, comprising conversions of length, area, volume, weight, stress, density, work; energy in mechanical, thermal, and electrical units; horse-power, and temperature." Only those who are familiar with graphic statics know what can be done by diagrams, but even they will be astonished at the wide range of conversions covered by Prof. Smith's graphic equivalence plates. The diagrams will principally aid the conversion of English and metric measures, and *vice versâ*, but they also represent the relations between different systems of English, and of French, measurement. We have always been attracted by the method of expressing equivalents by means of squared paper, and Prof. Smith's graphic tables have greatly increased our admiration of it.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Kinetic Theory of Gases.

I DO not feel as if those who heard me ask some questions at the British Association at Oxford, about the kinetic theory of gases, exactly understood my difficulties. They are those of an onlooker, and so they may be of general interest. As several of them have been fairly satisfactorily answered, it may be worth while stating the present position of such an onlooker as myself.

In the first place, consider the difficulty as to reversibility and as to the number of possible ways in which a system could be started on a reverse path so as to obtain a *given* initial state. This is, I think, completely answered in the way Mr. Larmor gives in his letter on p. 152. As well as I can recollect, Mr. Culverwell and I had been mutually satisfied by this kind of explanation previous to the meeting at Oxford, and it was not then referred to.

The question of reversibility lately started, as I understand it, has reference to the introduction of the postulate of chance in the deduction of the theorem about H. Mr. Burbury, in his recent letter, has indicated a proof of this theorem, in which he explicitly postulates chances, and so far justifies the possibility of proof on these lines. I understand that Mr. Culverwell is so far satisfied, and only asks for more, *i.e.* an extension of this form of proof to other cases than the simple one of colliding spheres.

Secondly, as regards the solar system, &c., I am not yet quite clear why a finite number of particles moving about for an indefinitely long time does not satisfy the conditions of the problem as usually stated, just as well as a large number of bodies for a short time. As to the necessity for *collisions* among the parts of a system, I cannot see why the earth, moon, Jupiter, and sun are not to all intents and purposes of the generalised coordinates in collision at present and always; and I desired to know why any other kind of collision is required for the application of the investigation. I think I now see, through conversations with Mr. Culverwell, where the existing investigations may fail to apply to solar systems. I may explain my position as follows. It was always, I knew, postulated that more than two particles should not be in collision at once, and I therefore asked how this could be an essential part of the investigation when applied to the case of air near the earth subject to gravitation. I did not see why the *earth* was not (so far as the generalised coordinates investigation was concerned) a particle in collision with every particle of the air during every one of their collisions with one another, and consequently violating the postulate requiring only *two* particles to be in collision simultaneously. I now understand that when dealing with gravitation and such like forces, these are supposed to be directed to *fixed* centres, and that in the case of a large particle like the earth this is very nearly true, but that it could not be even approximately true if we had three fairly equal particles acting upon one another simultaneously. This may also explain why the equal partition of energy does not hold in the solar system where the bodies do not act upon one another in pairs, but are all always subject to one another's action. This, as I understand, is also the reason why the direct distance law is not an exception to the equal partition of energy theorem. It also may explain how we can have water and steam in equilibrium with one another, notwithstanding the apparent *uniqueness* of the Boltzmann-Maxwell solution. From experience it would seem that when we can extend the investigation to the case of several bodies in simultaneous collision, we shall find that there are *three* solutions corresponding to the solid, liquid, and gaseous states. At the same time, some of the very general investigations that seem to me, as a physicist, as if they were intended to apply to complex molecules in collision with one another, and with a partition of energy amongst the atoms, appear to violate the postulate of collisions in pairs; for I find it hard to conceive of these molecular systems of atoms as other than systems, the various parts of which are held together by mutual actions, and which must consequently be considered to be in simultaneous collision with one another. This may be where the spectrum crux fails. Perhaps somebody would be so very kind as to point out where exactly in these generalised coordinate investigations the postulate of collisions in pairs is used, and so save lazy people like me the trouble of hunting it up.

This raises the third point as to how this difficulty about the spectral lines is to be surmounted. I cannot follow either Mr. Bryan's, or what I understood to be Mr. Larmor's view, that any help can be got by supposing spectral lines to be due to electromagnetic vibrations. The example Mr. Bryan gives of smooth solids of revolution is quite beside the point. In this case there is *no interchange of energy* between rotation round the axis of revolution and the other degrees of freedom. This is quite contrary to what we know to be the case in respect of ethereal and molecular energy. We know that radiations cause bodies to become cooler, and therefore there *is* interchange of energy. This could not be otherwise, as is evident from what we know of the mechanical forces—electric, magnetic, and electromagnetic—that interact between matter and ether. It is rather hard for Mr. Bryan to say that the *onus probandi* lies with physicists to explain exactly *how* transference takes place; surely the fact that transference does take place is sufficient to prove that a complete theory should take in both sets of coordinates—ethereal as well as material—and I should have thought that those formidable arrays of $dp_1\, dp_2\, .\, .\, .\, dp_n$ &c., of coordinates and momenta to the nth, with dots between to signify their indefinite number, should include everything of this kind that could possibly be required. Here, however, the postulate of collisions in pairs entirely breaks down, and thus shows a way out of this spectral difficulty. A second way was suggested to me, by whom I forget, at Oxford, namely, that the complicated systems of lines that we see in the spectrum—of iron, for instance—are so connected as to their amplitudes, periods, and phases, as to represent only a single coordinate. Anybody who has tried to expand a simple function in Fourier series will easily understand how a very simple motion might produce a fearfully complicated spectrum.

It seems, then, to me that the questions which need solving in our study of the dynamical foundations of thermodynamics at present are (1) how to explain spectra, and (2) how to deal with several bodies in simultaneous collision?

GEO. FRAS. FITZGERALD.

Trinity College, Dublin, December 19, 1894.

THE difficulties in the way of harmonising the spectroscopic phenomena of heated gases with the conclusions of the Boltzmann-Maxwell theorem of distribution of kinetic energy, appear to me to have been exaggerated.

This theorem asserts, as a purely dynamical proposition, that a very large number of, say, billiard balls, perfect as to sphericity and elasticity, having been set in haphazard motion in a space bounded or interrupted by perfectly elastic rigid surfaces, if the volume of free space be sufficiently large as compared with the total volume of the balls[1] will, if left to itself, tend to a certain state of density and velocity distribution, and having reached this state, will remain in it permanently. The billiard balls may be replaced by rigid bodies of any form, or indeed by material systems capable of any changes of shape or motion of the parts among themselves, and a corresponding proposition still prevails—one general property holding good in all cases, viz. that if u, v, w be the motions of translation of each system as a whole, m its mass, T its total kinetic energy, and n the total number of its degrees of freedom inclusive of the 3 of translation, then in the permanent state

$$\frac{m\overline{u^2}}{2} = \frac{m\overline{v^2}}{2} = \frac{m\overline{w^2}}{2} = \overline{\mathrm{T}}/n,$$

where $-$ denotes mean value throughout the whole medium.

Primâ facie there is a discontinuity in this abstract proposition unfitting it for the basis of physical investigation, *e.g.* the smallest possible want of perfect sphericity in the billard balls would appear to effect as complete a change in the physical properties of the medium as if each ball became an ellipsoid or tetrahedron, the mean $\frac{m\overline{u^2}}{2}$ being changed *per saltum* from $\overline{\mathrm{T}}/3$ to $\overline{\mathrm{T}}/6$, and the difficulties introduced by the spectroscope are founded upon this discontinuity. Doubtless we cannot make n fractional, but it should be remembered that the dynamical proposition only speaks of an *ultimate* state, and ignores the rate of approach to that state. The continuity of physical properties is maintained by attending to the continuity of change in this rate. This rate I have estimated for a particular case in the new edition of my short treatise on the subject, showing that there *may* be a *sensible* permanence long before the law of equal partition is established.

And, again, there is yet another point to be considered. The passage from the thermal to the optical properties resembles the passage from mere noise to music. Dynamically it is the passage from irregular, haphazard motion, *heat*, to regular periodic motion, *light*; the former must be decomposed into its equivalent harmonic motions, and the most important terms retained, but there would be no necessary relation between the number of these terms (sensible bright lines) and the number of degrees of freedom of the molecule.

H. W. WATSON.

[1] So large that the average number of cases in which three or more spheres are at any instant in collision is infinitely smaller than the number of cases in which two only are in collision.

The Horn Expedition to Central Australia.

In your issue of September 27, 1894, occurs a short notice of the work of the Horn scientific expedition to Central Australia. Reference is made therein to the discovery of a "new type of marsupial" by Dr. Stirling. The animal in question was found by Mr. South, a mounted trooper (or rather by his cat, who brought it into the house), at Alice Springs. By him it was presented on our arrival to Dr. Stirling, who had charge of the anthropological work of the expedition, by whom it was kindly handed on to me as officer in charge of the zoological department. The specimen was a male, and being desirous of securing more, I stayed behind the party, and by aid of the blacks procured two more specimens, both of them females. The animal, which lives in holes amongst the rocks and stones, is by no means common, as I had to offer considerable quantities of flour and tobacco to the blacks as a reward for its capture. After a number of them had been out hunting for several days the total result was two more specimens, though as these were females they formed a welcome addition to my zoological collections. As the expression, "a new type of marsupial," gives rise to too great expectations, it may be as well to state that it is merely a new species of the genus Phascologale, distinguished, amongst other points, by its remarkably fat tail and by the nature of the striated pads on the soles of its feet. I was able to make drawings of the animal alive, and on showing these to the blacks at Charlotte Waters, some 250 miles to the south of Alice Springs, they were at once greeted with cries of "Amperta," the native name for the animal which they took it to represent. Through the kindness of Mr. Byrne, the head of Charlotte Waters Telegraph Station, I have since been provided with specimens of the "Amperta," which on examination turns out to be the rare form—only as yet, I believe, known from a single specimen—described by Krefft under the name of *Chætocercus cristicanda*, and subsequently placed by Mr. Oldfield Thomas in the genus Phascologale.

These two species, and a new one of the genus Sminthopsis, which we secured amongst the sand-hills near Lake Amadeus, are the most important finds amongst the marsupials which, owing to the country traversed by us being in the main of a desert description, were by no means plentiful. In this region animals can only be secured in numbers after rain, an experience which, during three and a half months' wandering, did not fall to our lot. However, as one result of Mr. Horn's generous action in equipping the expedition, I hope to be able to give a fairly good general account of the fauna of the central desert region of Australia. Towards the close of the notice referred to, it is said that there is some doubt as to the manner of publication of our results. Mr. Horn's intention is, I believe, to issue a separate volume, the various parts of which will deal with the branches of science represented by the members of the scientific staff as follows:—

Prof. R. Tate (chairman of the scientific staff), geology and botany; Dr. E. C. Stirling, anthropology; Mr. C. Winnecke (leader of the expedition), surveying and meteorology; Prof. Baldwin Spencer, zoology; Mr. J. A. Watt, geology and mineralogy.

The volume will contain an accurate map, compiled by Mr. Winnecke, of the central district drained by the Finke river, and will, by means of the reproduction of photographs, illustrate some of the more important physiographic features of Central Australia. BALDWIN SPENCER.

Palæontology at the Royal School of Mines.

IN reading the excellent review of the biography of Sir R. Owen, which appeared in last week's NATURE, I observe an error which, though small, requires correction. It is stated that when Owen surrendered his appointments at the College of Surgeons he was "enabled to accept the lectureship on Palæontology at the Royal School of Mines, in 1857." The records of that Institution will show that Owen never held a lectureship there, nor was he in any way connected with the School.

The large theatre of the Museum of Practical Geology was frequently employed for other purposes than those of the School, by permission of the Director-General; and it was in virtue of such permission from Sir Roderick Murchison that Prof. Owen used the theatre for the delivery of his lectures on Palæontology to the public, in 1857 and subsequently. T. H. HUXLEY.

Eastbourne, December 27, 1894.

Eocene Fossils at Murren.

I HAVE read with surprise the extracts from the letter which you have received from Dr. Fellenberg on this subject. Of course it has long been known that there are Eocene strata at Murren. But below them lie calcareous rocks coloured on the Swiss map as Malm. These are so described on p. 211 of the "Livret Guide," published by the International Geological Congress which met this autumn at Zürich. During the subsequent excursion, under the able guidance of Prof. Renevier, Prof. Golliez, and M. Lugeon, we were taken to Murren and shown these rocks, and Prof. Golliez gave us the reasons which had led some geologists to regard them as Trias rather than Malm. It was in these calcareous beds that the layer containing nummulites was met with. The train was just starting, and we had to leave, but the find excited so much interest that M. Lugeon returned to Murren the next day, with some of the party, and verified the exact locality. JOHN LUBBOCK.

High Elms, Farnborough.

The Use of the Globe in Crystallography.

IN your issue of December 20, Mr. Buchanan revives a graphic method of crystallographic calculation which seems to have been used in the early part of the century (*vide* "Zur physichen Krystallonomie, &c.," Grassmann, 1829, p. 37), and claims that by use of the globe and *métrosphère* "every problem in the geometry of crystals can be solved with ease and accuracy."

Crystallographic angular measurements are said to be accurate if subject to a probable error of less than two or three minutes, and descriptions of inorganic substances are nowadays habitually published in which the probable errors are of this order. Although no details of Mr. Buchanan's method are given, it seems inconceivable that any graphic process of crystallographic calculation, involving triangulation on a sphere, could be accurately performed without the use of numberless tedious precautions and large and cumbrous apparatus.

It is usually more easy to grasp a good plane diagram of any solid figure than to understand and follow up explanations on the solid figure itself; the use of the latter is liable to lead to inaccuracy of expression and confusion of thought. Thus, when the sphere is used, the real meaning of the points which Mr. Buchanan describes as cataloguing the edges occurring on crystals, is not at once seen; using the plane projection, it is immediately apparent that these points are characteristic, not merely of the edges, but in a much wider sense, of the zones: they are merely the poles of the zone circles.

Further, the positions of the points representing the corners are dependent on the *sizes* of the faces concerned, which, as we teachers of crystallography are at infinite pains to impress on our students, have no crystallographic signification; these points, then, are not *characteristic* of the corners.

Similarly, the rather complicated piece of reasoning respecting "reciprocal inversion forms" simply yields the well-known result that in the cubic system, the octahedron truncates the corners of the cube. WILLIAM J. POPE.

"The Zoological Record."

IT has long been a matter of regret that the *Zoological Record* is not sold in separate parts; a specialist requiring any one part being required to pay for all the others, though they may be of no more use to him than so much waste-paper.

In order to remedy, to some extent, this unfortunate state of things, I am proposing (if sufficient support is forthcoming) to purchase the *Zoological Record* as published, and to issue the separated parts to subscribers. With this view, I would ask all those desiring any part (of the volume just issued, or of past volumes) of the *Zoological Record*, to communicate with me *as soon as possible*, stating *which part* they would be willing to subscribe for.

Although it is, of course, not intended to make a profit out of this scheme, it will nevertheless be necessary to charge slightly more for the separated parts than their proportionate value, as some parts are almost certain to remain unsold.

I am confident that this scheme will not in any way injure the Zoological Society; in fact, although they maintain the contrary, I am sure it would be to their advantage to issue the parts separately, if necessary at a slightly higher rate. At present subscribers are, I believe, mostly libraries and societies, requiring the whole volume. These would, of course, continue to subscribe for all parts, even if they were obtainable separately; while, on the other hand, all specialists who do not subscribe under the present arrangements would be practically certain to purchase those parts dealing with their own subjects, if obtainable at a moderate cost. If the proposed scheme meets with support, it will go a long way towards proving the justice of the foregoing contention, and in that case it will probably be possible to induce the Zoological Society to grant the concession for which many zoologists have for long been agitating.

Gravitation.

IN answer to Dr. Lodge's letter, I may state that Newton in his "Opticks" (Query 21) asks if an increase of density of the ether outwards from bodies will not account for gravitation, every body endeavouring to go from the denser parts of the medium towards the rarer; and if such increase of density may not, even at great distances, be effective, provided the elastic force of the medium be sufficiently great.

I do not think a tensile ether is contemplated in this theory of gravitation. Prof. Worthington's effect manifests itself only in a tensile liquid, and this constitutes its suggestiveness in connection with the hypothesis of a tensile ether. I have no such definite ideas to advance as are put forward in the "Opticks." J. JOLY.

The Feigning of Death.

THE curious condition of apparent death, assumed by the English grass snake, which Mr. G. E. Hadow describes (NATURE, December 6, p. 127), is one that I have frequently observed, but have always been puzzled to account for I hardly think that it has anything to do with simulation, or that it is voluntary, since I have seen snakes so affected when quite undisturbed in their cases. I have also observed precisely the same state in the common Italian snake. In my experience the condition only occurs in fairly hot weather, and when the snake has not fed for some time. This seems to point to a species of fainting fit, and I imagine that it is immediately induced by a disturbance of the cerebral circulation.

Peculiarities of Psychical Research.

IN reply to Prof. Pearson: (1) His remark about "scientific acumen" was not made *à propos* of M. Richet's experiments, but of those of the S.P.R.; and hardly any stress is laid on M. Richet's results, either by Mr. Gurney or Mr. Podmore. Mr. Gurney, on the contrary, expressly says: "Clearly no definite conclusion could be based on such figures." But if Prof. Pearson has made experiments which are equally striking in the opposite sense, I wish he would publish them, or communicate them to the S.P.R. (2) There was nothing in my letter to indicate that I under-estimated the importance of "abnormal distributions"; but I asked Prof. Pearson to say whether he had any reason to suppose such distributions might have occurred in the case in dispute. This he has failed to do—he has evaded the point. (3) Prof. Pearson descends to vague generalities except in regard to Dr. Oliver Lodge, who may be left to defend himself.

With the last paragraph of the letter, however, I heartily concur. There is nothing the S.P.R. would welcome more than intelligent and independent criticism. Only the critic would have to study the evidence first, and the Professor apparently has the "scientific acumen" to see that by doing so he would cut his own throat; for he would, *ipso facto*, become a psychical researcher! EDWARD T. DIXON.

Cambridge, December 29, 1894.

ON THE AGE OF THE EARTH.

IT has been thought advisable to publish the following documents. On October 12 I put my views before Prof. Fitzgerald and Dr. Larmor. The first paper is a copy of my letter to Dr. Larmor. It has now been edited a little, as originally it was rather hurriedly written. Some long mathematical notes, added on November 1, to prove the legitimacy of my approximate method of calculation, are now omitted, as Mr. Heaviside has given exact solutions, and has found that there is practically no difference between mine and the exact numerical answers. That Mr. Heaviside should have been able, in his letters to me during eleven days, to work out so many problems, all seemingly beyond the highest mathematical analysis, is surely a triumph for his new methods of working. Only for Prof. Fitzgerald's encouragement and sympathy, it is very probable that this document would never have been published.

I have sometimes been asked by friends interested in geology to criticise Lord Kelvin's calculation of the probable age of the earth. I have usually said that it is hopeless to expect that Lord Kelvin should have made an error in calculation. Besides, in every class in mathematical physics in the whole world since 1862 the problem has been put before students, and, as the subject is of enormous interest, if there had been any error it certainly would have been discovered before now.

I dislike very much to consider any quantitative problem set by a geologist. In nearly every case the conditions given are much too vague for the matter to be in any sense satisfactory, and a geologist does not seem to mind a few millions of years in matters relating to time. Therefore I never till about three weeks ago seriously considered the problem of the cooling of the earth except as a mere mathematical problem, as to which definite conditions were given. But the best authorities in geology and palæontology are satisfied with evidences in their sciences of a much greater age than the one hundred million years stated by Lord Kelvin; and if they are right, there must be something wrong in Lord Kelvin's conditions. On the other hand, his calculation is just now being used to discredit the direct evidence of geologists and biologists, and it is on this account that I have considered it my duty to question Lord Kelvin's conditions.

The original object of Lord Kelvin's investigation is usually forgotten. He sought to prove, and proved, that the earth is losing energy at a calculable rate. He said that the loss might be the loss of potential or chemical energy instead of sensible heat, or as well as heat, although he thought that a large proportion of potential or chemical energy was improbable; and it is only on the assumption that the earth is a cooling body losing energy originally only of the sensible-heat form, that his calculation of the age of the earth is based. Not only so, but also his earth is a homogeneous mass of rock such as we have on the surface, with the same conductivity and other heat properties. He starts with the knowledge that there is an average increase of temperature downwards in the earth of one Fahrenheit degree for every 50 feet. Assuming that the earth, a solid, was once at the uniform temperature of 7000° F., that its surface was suddenly brought to and kept at the temperature 0, and taking k/c (k being conductivity and c capacity for heat of unit volume, in year foot units) as 400, he finds that 10^8 years have sufficed to cause the temperature-gradient at the surface to be what it is now. He stated that the conditions were sufficiently represented by an infinite uniform mass of matter at 7000° F. with an infinite plane face kept at 0.

At first I preferred to consider a *globe* of 4000 miles radius of constant surface-emissivity to be cooling as if in an enclosure, kept at constant temperature. I made the emissivity infinite, and obtained Lord Kelvin's answer for temperature-gradient near the surface. When the emissivity is taken of a finite value, the time taken to produce the present temperature-gradient is less than Lord Kelvin's answer.

It is interesting to notice that if we take our enclosure to be at a zero of temperature which we can choose as we please, we have a method of using Fourier's expression in certain cases in which the emissivity is not constant. By no method of working does it seem probable that we shall greatly alter Lord Kelvin's answer.

Modification of Lord Kelvin's Conditions.

But, when we depart from homogeneity, when we assume that the interior of the earth may be of better conducting material than the surface rock in which the temperature-gradient is alone measured, we find a very different state of things from that considered by Lord Kelvin. The cooling from a constant temperature of an infinite mass bounded by a cold plane face, a slice of which near the surface is of material different from the rest of the infinite block, is a problem difficult to attack mathematically. But if the slice is thin, or if much time has elapsed, the following artifice leads to a solution.

Imagine an infinite homogeneous block, originally at temperature V_1, whose surface is kept at 0. If x_1 is sufficiently small and t great, we may neglect the exponential term, and (v being temperature and t time, and x the distance from the cold face)

$$\frac{dv}{dx} \text{ at } x_1 = V_1 \div \sqrt{\pi\kappa_1 t}; \; v_1 \text{ at } x_1 = V_1 x_1 \div \sqrt{\pi\kappa_1 t}.$$

Rate of flow of heat across unit area at $x_1 = k_1 V_1 \div \sqrt{\pi\kappa_1 t}$. I take k as conductivity, and κ as conductivity divided by capacity for heat of unit volume.

Now take another such homogeneous infinite block of different material, and use the letters with affix 2 instead of 1. Let the time be the same in both. Let the surface slice from x_1 to 0 in the first, and from x_2 to 0 in the second be considered. We can, by taking proper values of V_1 and V_2 and x_1 and x_2, make the rates of flow of heat equal and the temperatures equal at x_1 and x_2:

$$k_1 V_1/\sqrt{\kappa_1} = k_2 V_2/\sqrt{\kappa_2} \text{ and } V_1 x_1/\sqrt{\kappa_1} = V_2 x_2/\sqrt{\kappa_2}$$

Hence $k_1 \div x_1 = k_2 \div x_2$. Thus if $nk_2 = k_1$, we take $nx_2 = x_1$.

Now we can take the slice x_2 to 0 from the second block and let it take the place of the slice x_1 to 0 on the first block. The artificial block so produced will go on cooling, its outside face being kept at 0_1. But we shall have at the point of junction a sudden multiplication of dv/dx. In fact, dv/dx will be what it used to be towards the interior, but will be n times as great towards the surface. It is of no consequence what the value of κ_2 is, if times are great and slices thin, the only important thing is that k_1 shall be n times k_2. The application of the result is obvious:—

Let the interior of the earth be a uniform sphere, uniformly heated to 7000° F. Take its κ as m times what Lord Kelvin took it, then an increase of temperature downwards from the surface of 1 F. degree for every 50 n feet would be produced in $10^8 n^2/m$ years. Take its k as n times what Lord Kelvin takes. Now if we imagine a skin removed and replaced by one of $1/n$th of the thickness and $1/n$th of the conductivity, that is, take it of Lord Kelvin's conductivity of rock, the surface slope will be 1 in 50, what it is now, and Lord Kelvin's time will be increased in the proportion n^2/m.

Considering the great differences in conductivity of such bodies as we know, it is quite conceivable in our knowledge and ignorance of the interior of the earth that n^2/m may be considerable even now, and probably was very considerable in past times. Roughly we may say that Lord Kelvin's age of the earth, 10^8 years, ought to be multiplied by two to six times the ratio of the internal conductivity to the conductivity of the skin.

I am not in a position to criticise the arguments from tide phenomena which Lord Kelvin or Mr. Darwin would now put forward on the subject of much internal fluidity of the earth. The argument from precession has been given up. Of course much internal fluidity would practically mean infinite conductivity for our purpose. But there is no doubt of a certain amount of fluidity inside even now, and taking it that the inside of the earth is a honeycomb mass of great rigidity, partly solid and partly fluid, we have reason to believe in very much greater quasi-conductivity inside than of true conductivity in the surface rocks, and if there is even only ten times the conductivity inside, it would practically mean that Lord Kelvin's age of the earth must be multiplied by 56.[1]

If we imagine the earth perfectly conducting inside with a thin covering, say 60 miles thick, of rock, such as we know it on the surface, we must leave Lord Kelvin's infinite mass and study the sphere. Indeed, if we take it that we have now an infinite mass at 7000° F. of infinite conductivity, cooling through rock of from 60 to 70 miles thick with a constant gradient of 1° for every 50 feet, we can imagine that this state of things has existed for an infinite time, and any original distribution of temperature in the rock would settle down to such a state.

Taking, then, an internal sphere of infinite conductivity[2] (and working in C.G.S. Centigrade units), its specific heat 0·2, and the conductivity of the rock 0·002, I find that if at the beginning of time there was an increase of 1° Centigrade in 45 feet, and now there is an increase of 1 Centigrade degree in 90 feet, the lapse of time is 28,930 million years, or 290 times Lord Kelvin's age, and the core has cooled from 8000 to 4000 degrees. Or, again, in the last 10^8 years the gradient has only diminished by 1/400th of its present value, and the core has only changed from 4010 to 4000 degrees.

I do not know that this speculation is worth much, except to illustrate in another way the augmented answer when we have higher conductivity inside. It would evidently lengthen the time if I assumed that the temperature-gradient was not uniform in the shell, but the exact mathematical calculation is so troublesome that I have not attempted it.[3]

JOHN PERRY.

31 Brunswick Square, London, W.C., October 14.

October 22, 1894.

The reasoning in my paper was applied either to infinite blocks of cooling material or to a sphere with an internal core which has infinite conductivity. At the time of writing I did not see my way to the consideration of a sphere with a core of finite conductivity and a shell of rock as a covering, but the case is really easy to work when the shell is only a few miles in thickness, as will be seen below.

PROBLEM.—A sphere of radius R = $6{\cdot}38 \times 10^8$ centim. of conductivity $k = 0{\cdot}47$ (or 79 times that of surface-rock) and $k/c = 0{\cdot}16464$ (or 14 times that of surface-rock), has upon it a shell of rock of thickness 4×10^5 centim. (about $2\frac{1}{2}$ miles). The whole mass was once at a temperature V = 4000° C., and suddenly the outside of the shell was put to 0° C. and kept at that. Find the time of cooling until the temperature-gradient in the shell has become 1 Centigrade degree in 2743 centim. (or 1° F. in 50 feet).

Now, if we are allowed to assume that the shell very rapidly acquired and retained a uniform temperature-gradient throughout its thickness, and it is easy to show that this assumption is allowable (or if not, then the discrepance is in favour of a greater age for the earth), the problem is exactly the same as this:—The above-mentioned sphere has no shell of rock round it, but emits heat to an enclosure of 0° C., the constant emissivity of its surface[4] being $E = 1{\cdot}475 \times 10^{-8}$; find the time in which the surface-temperature v' becomes 146° C.

This problem is solved by Fourier, who gives for the temperature at the distance r from the centre

$$v = \frac{2VER}{k} \Sigma \frac{\sin er/R}{er/R} \frac{\epsilon^{-ke^2t/cR^2}}{e \operatorname{cosec} e - \cos e},$$

where in the successive terms the values of e to be taken are the successive roots of the equation

$$e/\tan e = 1 - ER/k.$$

In the present case $ER/k = 20$, and e_1, e_2, e_3, &c., are nearly π, 2π, 3π, &c. I have, however, taken the actual values of e_1 and e_2—two exponential terms, only, being of importance, and I find that, if $t = 96 \times 10^8$ years,

$$v' = \underset{\text{1st term}}{142{\cdot}7} + \underset{\text{2nd term}}{5{\cdot}65} = 148{\cdot}4;$$

so that the age of cooling to the present temperature-gradient is more than 96×10^8 years.

[1] Observe that, even if we assume that there is the same conductivity inside and outside, inasmuch as the density is greater, c is greater, say 3 times as great, and even without the assistance of increased conductivity inside, we have 3 times Lord Kelvin's age. I admit that all such speculation as to the value of c is too vague to be of much importance.

[2] If θ_0 and θ were the internal temperatures at the times t_0 and t, if b is the thickness of the crust and R the radius of the internal sphere, if s is its specific heat and ρ its density and k its conductivity,

$$t - t_0 = \frac{Rbs\rho}{3k} \log \frac{\theta_0}{\theta}.$$

[3] If ·006 be taken as the conductivity of rock, the times are only a third of what I have given.

In connection with this matter I notice that in Lord Kelvin's very short paper, entitled "The 'Doctrine of Uniformity' in Geology briefly Refuted," read before the Royal Society of Edinburgh in 1865, he finds:—"But the heat which we know, by observation, to be now conducted out of the Earth yearly is so great that if this action had been going on with any approach to uniformity for 20,000 million years, the amount of heat lost out of the Earth would have been about as much as would heat, by 100° Cent., a quantity of ordinary surface-rock 100 times the Earth's *bulk*." (The italics are mine.) In his address on "Geological Dynamics," Part II., published in 1869 (p. 126, vol. ii. "Popular Lectures and Addresses"), he calculates the total amount of energy which *may* once have been possessed by the Earth mass, partly gravitational and partly chemical, as 'being about 700 times as much heat as would raise the temperature of an equal *mass* of surface-rock from 0° to 100° Cent.' (The italics are mine.) I do not think that these two statements have ever before been put in juxtaposition. Comparing them, we may say that, according to Lord Kelvin's own figures, if the present action had been going on with any approach to uniformity for 10^8 years the amount of heat lost by the Earth would have been the 1/7800th part of the whole energy which the whole Earth may once have possessed, or 1/2230th part of what Lord Kelvin gives as an estimate, an over-estimate he calls it (but he says that it is not possible to make one much less vague), of the whole amount of heat at present in the Earth. I mention this because some mathematical physicists believe that Lord Kelvin based his age of the Earth upon a calculation of this total loss. He only used it in opposition to the extreme doctrine of uniformity for the past 20,000 million years (a doctrine which is not now believed in by any geologist), but it lends no support to his calculated age of the Earth).

All through this paper I give 10^8 years as Lord Kelvin's age of the Earth. His own words (*Trans. R.S. Edin.*, 1862 (*j*) are:—"We must, therefore, allow very wide limits in such an estimate as I have attempted to make; but I think we may with much probability say that the consolidation cannot have taken place less than 20,000,000 years ago, or we should have more underground heat than we actually have [he means a more rapid increase of temperature downwards], nor more than 400,000,000 years ago, or we should not have so much as the least observed underground increment of temperature." Taking the average diffusivity for heat of the Edinburgh experiments, he finds (*r*) that the present temperature-gradient of 1 Fahr. degree for every 50 feet gives a life of 10^8 years.

[4] Because if v' is the surface-temperature of the sphere and b the thickness of the shell of rock, v'/b was the surface-gradient in the shell and v'/b multiplied by conductivity of rock is equal to Ev'.

If we take k as 195 times that of the surface-rock, and k/c as 35 times that of the surface-rock, and if the shell has a depth of $3 \cdot 272 \times 10^6$ centimetres (about 20 miles), the time of cooling until the temperature-gradient is 1 Cent. degree in 2743 centim. is *more* than 127×10^8 years."[1]

I kept no copy of the letter which I sent to Prof. Tait with the foregoing document. In it I explained my difficulty in getting Lord Kelvin to re-consider the internal heat question, and I asked for his advice.

Extract from Letter of Prof. Tait, November 22, 1894.

. . . my entire failure to catch the *object* of your paper. For I seem to gather that you don't object to Lord Kelvin's mathematics. Why, then, drag in mathematics at all, since it is absolutely obvious that the better conductor the interior in comparison with the skin, the longer ago must it have been when the whole was at 7000° F.: the state of the skin being as at present?

I don't suppose Lord Kelvin would care to be troubled with a demonstration of *that*.

As to the validity, or more properly the *plausibility* of his or your assumptions, I don't suppose anyone will ever be in a position to judge. He took the simple and apparently possible case of uniform conductivity all through—having no data whatever. What if he had assumed, as he was quite entitled to do, that the conductivity diminishes *very fast* with rise of temperature?

But I need not say any more, as I seem to have entirely missed your point.

Letter to Prof. Tait, November 26, 1894.

DEAR PROF. TAIT,—I should have been on the whole better satisfied if you had opposed my conclusions. You say I am right, and you ask my object. Surely Lord Kelvin's case is lost, as soon as one shows that there are *possible* conditions as to the internal state of the earth which will give many times the age which is your and his limit. . . . What troubles me is that I cannot see one bit that you have reason on your side, and yet I have been so accustomed to look up to you and Lord Kelvin, that I think I must be more or less of an idiot to doubt when you and he were so "cocksure." The argument from the sun's heat seems to me quite weak. Even a geologist without mathematics can see that the time given by Lord Kelvin will be increased if we assume that in past times the sun radiated energy at a smaller rate than at present, much of its mass being possibly cold and in the meteor form, and the rate may have greatly varied from time to time. This is not only possible but probable, and it is for you and Lord Kelvin to prove a negative.

Then the Tidal Retardation argument! Even if your rate of retardation is correct, the real basis of your calculation is your assumption that a solid earth cannot alter its shape (diminishing its equatorial radius by a few miles) even in 1000 million years, under the action of forces constantly tending to alter its shape, and yet we see the gradual closing up of passages in a mine, and we know that wrinkling and faults and other changes of shape are always going on in the solid earth under the action of long-continued forces. I know that solid rock is not like cobbler's wax, but 10^9 years is a very long time, and the forces are great!

I had thought these two arguments to be mere supporters of the internal heat one which I took to be the only important one, like a diamond whose pure sparkle was brought into relief by two rubies.

If I were alone in my opinion, I should still have the courage, I think, to write as I do; but as I have already told you, I did not venture to write and speak to Lord Kelvin, or write to you until I found that so many of my friends agreed with me—Fitzgerald, O. Reynolds, Larmor, Henrici, Lodge, Heaviside, and many others. Fitzgerald is the only man to whom I have mentioned my notion about the sun's heat, but he quite agrees with me. I have not put before him my notion about the Tidal Retardation argument. . . .

November 27.

DEAR PROF. PERRY.—I should like to have your answers to *two* questions:—

(1) What grounds have you for supposing the inner materials of the earth to be better conductors than the skin?

(2) Do you fancy that any of the *advanced* geologists would thank you for 10^{10} years instead of 10^8? Their least demand is for 10^{12}:—for *part* of the mere secondary period!

Yours truly,
P. G. TAIT.

November 29, 1894.

DEAR PROF. TAIT,—It is for Lord Kelvin to prove that there is *not* greater conductivity inside. Nevertheless I will state my grounds:—

1 (*a*). In page 6 of the paper sent you I say "I am not in a position to criticise the argument from tide phenomena which Lord Kelvin or Mr. Darwin would now put forward on the subject of much internal fluidity of the earth. The argument from precession has been given up. Of course, much internal fluidity would practically mean infinite conductivity for our purpose. But there is no doubt of a certain amount of fluidity inside, even now, and taking it that the inside of the earth is a honeycomb mass of great rigidity, partly solid and partly fluid, we have reason to believe in very much greater quasi-conductivity inside than of true conductivity in the surface rocks."

1 (β). Even if we assume perfect solidity, and even neglecting our knowledge of much iron—surely there can be no doubt of the conductivity of rock *increasing* with the temperature. From the analogies with electric conduction, one would say, without any experimenting, that as a metal diminishes in conductivity with increase of temperature, so a salt, a mixture of salts, a rock, may be expected to increase in conductivity with increase of temperature. I presume that Everett's book is recognised now as giving the most exact information on these subjects. He nowhere suggests that rock diminishes in conductivity with temperature. Every case he gives shows an increase. I have made out the following table from the only quotations which Everett gives from Dr. Robert Weber; only five cases, but probably representative.

Percentage increase for a rise of 100° Centigrade.

	In conductivity.	In specific heat.
Micaceous gneiss ...	48·0	23·6
Mica schist	136·4	24·4
Eurite	1856	35·7
Gneiss	21·4	61·5
Micaceous schist ...	94·5	35·4
Average ...	431	36·1
Average, leaving out Eurite	75	36

Even if the conductivity and specific heat did not alter, inasmuch as the internal density is greater, the volumetric capacity is greater; and if it is three times as great, we have three times Lord Kelvin's age. In fact, the rule given at page 4 of my paper is the same as this:—If the conductivity inside is

[1] The general expression for any case is this:—A sphere of radius R of conductivity nk and capacity per unit volume mc/n surrounded by a shell of thickness b, conductivity k, and capacity for heat per unit volume c; take $E = k/b$: when is v', the temperature at the surface, equal to $b/2743$?

$$\frac{e}{\tan e} = 1 - R/bn.$$

Then

$$\frac{b}{2743} = \frac{2VR}{bn} \Sigma \frac{\sin e}{e} \frac{\sin e}{e - \frac{1}{2} \sin 2e} \epsilon^{-ke^2t/cR^2}$$

enables t to be calculated. It would no doubt be possible, but it would hardly be worth while, to find the values of n and b which would give a maximum value for t. In one of the above cases I took e nearly π, and in the other $\pi/2$.

I am quite unable to attack the problem of the cooling of a sphere from an arbitrary initial condition, in which the diffusivity for heat is an arbitrary function of r.

There is some distribution of k/c which would give a greater age to the Earth than any other, but, again, it would hardly be worth while to spend much time on the problem. My purpose has not been to fix a higher limit to the age of the Earth; it has only been to show that such a higher limit must be greater than some hundred of times one hundred million years.

Some of my friends have blamed me severely for not publishing the above document sooner. I was Lord Kelvin's pupil, and am still his affectionate pupil. My B.A. lecture on Spinning Tops was stolen from him, as I duly acknowledged when it was published. He has been uniformly kind to me, and there have been times when he must have found this difficult. One thing has not yet happened: I have not yet received the thirty pieces of silver.

n times the conductivity outside; if the specific heat inside is s times the specific heat outside; if the density inside is d times the density outside; then Kelvin's age of the earth is increased $n\,s\,d$ times. . . It is not likely that Dr. Weber's rate of increase would be constant to such a temperature as 4000° C.; but the electric analogue allows us to imagine a greater and greater rate of increase at higher temperatures; therefore it is in Lord Kelvin's interest to take Weber's rate. Now at 4000° C. the conductivity would be [leaving out eurite, which seems abnormal and too much in my favour], thirty times as great as it is at the surface; the specific heat would be 14½ times as great, and taking the density as three times, we have, even for a *perfectly solid* earth an age 1300 times the age given by Lord Kelvin.

2. In answer to your second question, Lord Kelvin completely destroyed the uniformitarian geologists, and not one now exists. It was an excellent thing to do. They are as extinct as the dodo or the great auk.

I have met many advanced geologists, and not one of them demands more than 1,000,000,000 years. Probably Sir Archibald Geikie is the most representative of the geologists who have studied this question, and he never (in recent years) seems to have desired even as much as 1,000,000,000 years. (See his address as President of the British Association.) The biologists have no independent scale of time; they go by geological time. According to Huxley, less than 1,000,000,000 years is enough as the age of life on the earth.

But surely the real question now is not so much what the geologists care about, as—Had Lord Kelvin a right to fix 10^8 years, or even 4×10^8 years, as the greatest possible age of the earth?

Yours truly,
JOHN PERRY.

December 6, 1894.

DEAR PROF. TAIT,—Prof. Fitzgerald has pointed out to me that the five rocks given by Everett are not to be found in his 1891 edition. I quoted from his 1886 edition. I therefore wrote to Everett, asking why he had left them out—was there a mistake? He writes to say: "I copied Weber's data from a copy of his paper which was, and may be still, in my possession, having been sent me through the post, probably by the author, or possibly by Dr. Stapff, the geologist of the St. Gothard Tunnel, with whom I had much correspondence in underground temperature. You seem to assume, in writing to Tait, that I picked out samples of Weber's results; but my recollection is that I gave everything without reservation.

"I did not reproduce his results in the 1891 edition, and I cannot remember all my reasons for dropping them. On comparing them with other people's, which I give, they appear to be much too small. There is such a mass of conduction results in my book, that I was on the look-out for something that might be omitted.

"I have just referred to the foreign translations of my book. The German edition, published in 1888, gives only a page of conductivities of solids, and includes among them one of R. Weber's, namely Glimmerschiefer ·000733 + ·000010 t. The Russian edition, brought out by editors who took tremendous pains in verifying and correcting references, gives my list of Weber's results exactly as it stands in my book, the sign of the temperature coefficient being positive in every case. I do not know of any direct evidence as to the variation of rock conductivity with temperature except R. Weber's, but there is something approaching to direct evidence in the comparison of George Forbes' results with Herschel and Dunn's (see my 1891 edition, pp. 126, 129). Forbes found at − 10° C. the conductivity of white marble to be ·00115, black marble ·00177. Dunn and Herschel found at the temperature of hot water, marbles, &c., ·0047 to ·0056 (see Forbes' remark, quoted at p. 129).

"You have built a very lofty edifice on the basis of Weber's results, and extrapolation is proverbially a risky process, but I consider you have established a strong presumption in favour of the increase of rock conductivity with temperature."

I did not know, when writing to you on November 26, that the Rev. M. H. Close, M.A., had (R. Dublin Soc., Feb. 1878) put forward in great detail the reasons which I gave you shortly, against the tidal retardation argument. I thought they were my own. I notice that this gentleman assumes that increased conductivity inside would help Lord Kelvin, and indeed I cannot help thinking that, without mathematics, almost anybody would be of the same opinion—in spite of what you say in your first letter. I know that Lord Kelvin himself did not seem to think me right when—after I had sent him the documents—I talked to him at Cambridge.

I remain, yours truly,
JOHN PERRY.

Copy of a Letter from Lord Kelvin.

The University, Glasgow, December 13, 1894.

DEAR PERRY,—Many thanks for sending me the printed copy of your letter to Larmor and the other papers, which I found waiting my arrival here on Saturday evening. I have been much interested in them and in the whole question that you raise, as to the effect of greater conductivity and greater thermal capacity in the interior. Your $n^2 \div m$ theorem is clearly right, and not limited to the case of the upper stratum being infinitely thin. Twenty or thirty kilometres may be as good as infinitely thin for our purposes. But your solution on the supposition of an upper stratum of *constant* thickness, having smaller conductivity and smaller thermal capacity than the strata below it, is very far from being applicable to the true case in which the qualities depend on the temperature. This is a subject for mathematical investigation which is exceedingly interesting in itself, quite irrespectively of its application to the natural problem of underground heat.

For the natural problem, we must try and find how far Robert Weber's results can be accepted as trustworthy, and I have written to Everett to ask him if he can send me the separate copy of Weber's paper, which it seems was sent to him some time before 1886; but in any case it will be worth while to make farther experiments on the subject, and I see quite a simple way, which I think I must try, to find what deviation from uniformity of conductivity there is in slate, or granite, or marble between ordinary temperatures and a red heat.

For all we know at present, however, I feel that we cannot assume as in any way probable the enormous differences of conductivity and thermal capacity at different depths which you take for your calculations. If you look at Section 11 of "Secular Cooling" ("Math. and Phys. Papers," vol. iii. p. 300), you will see that I refer to the question of thermal conductivities and specific heats at high temperatures. I thought my range from 20 millions to 400 millions was probably wide enough, but it is quite possible that I should have put the superior limit a good deal higher, perhaps 4000 instead of 400.

The subject is intensely interesting; in fact, I would rather know the date of the *Consistentior Status* than of the Norman Conquest; but it can bring no comfort in respect to demand for time in Palæontological Geology. Helmholtz, Newcomb, and another, are inexorable in refusing sunlight for more than a score or a very few scores of million years of past time (see "Popular Lectures and Addresses," vol. i. p. 397).

So far as underground heat alone is concerned you are quite right that my estimate was 100 millions, and please remark ("P. L. and A.," vol. ii. p. 87) that that is all Geikie wants; but I should be exceedingly frightened to meet him now with only 20 million in my mouth.

And, lastly, don't despise secular diminution of the earth's moment of momentum. The thing is too obvious to every one who understands dynamics.

Yours always truly,
KELVIN.

JUPITER.

JUPITER being now near opposition, and having an apparent diameter of 47″·7, is displayed as a very brilliant object in the heavens, and his northerly declination of 23 degrees enables him to remain above the horizon for a period of 16½ hours.

During the few ensuing months, the observation of his belts and spots will enlist a large amount of attention, for there is probably no other planetary object which exhibits a more diversified and variable aspect. One feature of the present observations will be important as enabling comparisons to be made as to the rates of motion of the various white and dark spots in this and preceding oppositions. No doubt many of the surface markings now existing are identical with those observed some years ago. From 1878 to 1882 the prominent apparition of the red spot incited observers to fully investigate the phenomena of the different formations, and they were found to be very discordant in their rates of velocity. The red spot and equatorial white spots were evidently subject to a marked retardation, causing their rotation periods to increase with the time.

As to the red spot, the slackening rate of motion it exhibited in the earlier years of its presentation, appears not to have been maintained since 1886, for Mr. Marth's adopted period of 9h. 55m. 40·63s. (equivalent to a daily rate of 870°·27) has correctly represented its mean motion during the last eight years. There have been, it is true, some marked deviations from the mean rate, for in the years from 1886 to 1890 the motion became accelerated and corresponded to a rotation period of about 9h. 55m. 40·2s., but in the three following years it slackened again, and since 1891 the period has been about 9h. 55m. 41·5s.

At the present epoch the spot is extremely feeble in its visible outlines, but on a really good night its elliptical form can be distinctly traced, and it does not appear to have materially changed either in its shape or dimensions since 1879. Its following end is decidedly the plainest, and its southern borders have lately been conjoined with a grey belt in about latitude 30° south. The commingling of the spot and belt has been noticed here on previous occasions, and it is certain that on its southern side the spot exerts very little of the repellent influence so often ascribed to it. On the contrary, the belts on the equatorial side of the spot always run clear, and abruptly bend north to allow of a clear white interval between the spot and belt. The S. border of the spot and S. belt were apparently in touch early in the past autumn, for Mr. Barnard, observing the red spot with the 36-inch refractor of the Lick Observatory, says: "The belt south of it seems to be in contact, if it does not actually overlap it slightly." The same thing was noticed as long ago as October 31, 1893, by the aid of the 16-inch refractor of the Goodsell Observatory, Minnesota, when the observers wrote "the great red spot was seen by us, and the colour was exactly the same as that of the belt just to the south of it, and the two objects merged into one another without the slightest change in intensity of colour."

The spot now arrives at mid-transit two or three minutes after Mr. Marth's zero meridian, as the following observations made here will indicate:—

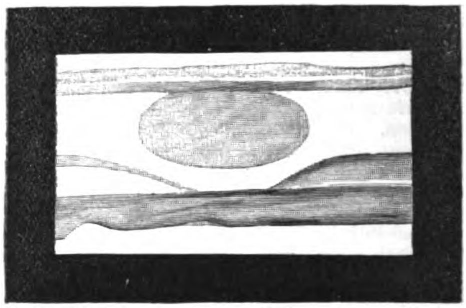
1894	Mid-transit of spot. h. m.	Follows Marth's zero meridian. m.	Long. of spot. °
November 25 ...	... 10 50 ...	... 4·2 ...	... 2·9
December 12 ...	... 9 46 ...	... 1·2 ...	... 0·7
19 ...	... 10 33 ...	... 3·5 ...	... 2·1

It is well known that the perception of a delicate planetary marking depends in a very great measure on the quality of the definition. On an indifferent night the red spot is practically invisible, but with steady air and a sharp image the familiar pinkish ellipse, now representing that object, shows up distinctly in the remarkable concavity of the great southern equatorial belt. The latter configuration always offers an excellent guide to the position of the spot, but its appearance is not symmetrical, the following side of it being much more strongly developed than the side preceding the spot.

The impending disappearance of the latter has been suggested by several observers from its loss of tone during the last few years, but there seems to be no tangible reason to suppose that we are on the point of losing this truly singular object. It is indeed utterly impossible to predicate anything definite as to its future history. The facts gleaned during past observations are not of a character to guide us to any reliable conclusion. Its present faintness may be but the prelude to a more marked manifestation, for variation of tint is certainly one of its leading peculiarities. It is doubtless the same object as the the ellipse seen by Gledhill and Mayer in 1869 and 1870, and quite possibly the same formation was figured by Dawes in 1857 and in subsequent years. At any rate the resemblance of the objects is eminently suggestive, and altogether too striking to be disregarded.

About fifteen years ago the equatorial zone of Jupiter exhibited phenomena proving it to be in a state of considerable activity. There were white and dark spots, wisps of dark material, veins of bright matter, and other irregularities all in condition of rapid change, and imparting a very broken and variegated aspect to the northern side of the great southern equatorial belt. To-day the indications are essentially different. The light tint of the equator seems pretty even, and exhibits few noticeable irregularities. Precisely on the equator there is a dark belt like a narrow pencil line, but it is not now continuous right round the disc. The chief seat of energy appears to have been transferred to the northern side of the great northern equatorial belt.

Dark spots (some of them almost black, like satellite shadows) and white patches, with other details of structure, are plentifully arrayed in the northern equatorial belt. The white spots I observed here in 1885 and 1886, and they have persistently maintained themselves ever since. Their rotation period in 1886 was about eight



1894 November 25, 10h. 9m., 10-inch reflector, power 252.
Region of Red Spot.

seconds less than that of the red spot, but in 1890–91 I found it only 2·6 seconds less. At present the period is still a little less, and there are a number of black spots in the same latitude, and subject to the same drift. One of the most conspicuous of the black spots precedes the red spot about 3h. 20m., and one of the chief white spots precedes the red about 2h. I have secured the following observations of this pair of objects:—

Black spot. 1894.	Mid transit. h. m.	Long. °	White spot. 1893.	Mid transit. h. m.	Long °
Nov. 5 ...	10 57 ...	239·1	Nov. 23 ...	10 0 ...	303·4
15 ...	9 10 ...	238·2	1894.		
17 ...	10 47 ...	237·6	Nov. 5 ...	12 16 ...	286·9
29 ...	10 39 ...	237·7	15 ...	10 31 ...	287·2
Dec. 4 ...	9 42 ...	235·1	25 ...	8 45 ...	287·0
18 ...	11 14 ...	236·5	Dec. 19 ...	8 24 ...	284·2

The northern temperate belt on which in 1880 and 1891 many rapidly moving black spots appeared, is now in close contiguity with the great northern belt, and blends with it in certain places. A few years ago the two belts were separated by a bright zone.

There is a narrow spotted belt in about latitude 35° north. In 1892 and on subsequent occasions I noticed this belt beaded with numerous dark spots, but I have not made a sufficient number of observations to determine the rotation period. This belt forms a delicate object; it is very narrow, and the spots extremely small. In bad air it is quite obliterated. Only a few observers appear to have noticed this northerly belt and its beaded aspect, but it has been an interesting feature of the planet during the last two years.

In the southern hemisphere and further south than the red spot, there are some dark condensations and white spots, with a rotation period of about 9h. 55m. 20s.

The S. region of the great N. belt exhibits interruptions in the form of very bright streams of material dividing the belt in an oblique direction relatively to the equator. These appearances show rapid changes from day to day, and I have not yet computed the rotation period satisfactorily, but it is obviously very different to that of the red spot. Five observations of these luminous encroachments on the belt have been secured here, as follow :—

	Mid-transit. h. m.	Long. °
November 8	11 0	332·0
15	12 31	359·7
29	9 47	206·1
December 4	8 1	174·1
19	9 33	325·8

It is intended to make a closer study of the variable aspect and rate of velocity of these singular formations.

We may depend upon it, from the number of interesting markings displayed on the planet, that there will be no abatement of useful observations during the present apparition. There is always something new to record, and objects previously known require attentive watching with reference to the differences in their rotation periods. Whether the theorem that the longer an object remains visible the slower becomes its velocity is true or not, cannot be definitely said, but the behaviour of the red spot has not altogether supported the idea. A vast amount of new evidence is required as to the phenomena affecting the surface markings of Jupiter; he presents an ample field both for the observer and the theorist.

W. F. DENNING.

NOTES.

SCIENCE is represented in the list of New Year honours by Mr. W. H. White, C.B., F.R.S., the Director of Naval Construction, who has been promoted to a Knight Commandership of the Bath. Two other Fellows of the Royal Society, Dr. J. Russell Reynolds, President of the Royal College of Physicians, and Dr. Eric Erichsen, formerly President of the Royal College of Surgeons, have each had the honour of a Baronetcy conferred upon them.

THE cross of Commander of the Order of the Ernestine House of Saxony, second class, has been conferred upon Dr. Edward S. Holden, Director of the Lick Observatory, for his services to science. This Order was founded in 1690, reorganised in 1833, and is conferred upon persons holding high official positions, either military or civil. At present there are eighteen Commanders of this class in Germany.

THE fund for the proposed statue to the late Dr. Charcot will probably soon be closed; as it is announced that thirty-five thousand francs have been collected, and this is sufficient to warrant the ordering of the statue. In all probability, a statue will be erected to Helmholtz, for it is reported that, at the recent celebration in Berlin, the German Emperor offered to head a subscription list for that purpose with a donation of ten thousand marks.

THE Paris Chemical Society has (says the *Chemist and Druggist*) recently come into possession of a legacy from M. Rigout, formerly of the École des Mines, who bequeathed to the Society an income of twelve hundred francs per annum, of which a portion is to be set aside for an annual prize to be awarded in connection with inorganic chemistry. M. Rigout declines to allow his name to be attached to this legacy, but asks to have it named the Edouard Rivot prize, in memory of his former Professor. It is worthy of mention that a short time ago M. Silva, late Professor at the School of Arts and Manufactures, left his library and modest fortune to the same Society "out of gratitude for the kindness met with in the French scientific world."

THE death is announced of M. Frederik Johnstrup, Professor of Mineralogy in Copenhagen University, at seventy years of age.

DR. F. KOHLRAUSCH, Professor of Physics in Strassburg University, has been appointed Director of the Imperial Physico-Technical Institute at Berlin, in succession to Helmholtz.

INCREASED facilities for instructing in the science and art of agriculture are gradually being given to the Technical Education Committees in various parts of the country. We are glad to see it announced that Earl Cowper, chairman of the Hertfordshire County Council, has offered to place a farm of nearly 300 acres, with residence and buildings, at the disposal of the Council, rent free, for the purpose of providing practical instruction in agriculture, on condition that the County Council stock the farm and work it. Lord Cowper has also undertaken to erect a laboratory and the necessary dormitories. A sub-committee of practical agriculturists has been appointed to consider his lordship's offer and report to the Council upon it.

A NEW society has just been formed in Paris for the purpose of subterranean exploration, to be called "La Société de Spéléologie." Its projector is M. E. A. Martel, whose works, "Les Abîmes" and "Les Cévennes," may be familiar to some readers of NATURE. In his papers read before the French Association for the Advancement of Science at Besançon in 1893, M. Martel warmly set forth the claims of underground investigation, and the light that might thereby be thrown upon geology, palæontology, and kindred subjects. Indeed, as readers of the works just mentioned are aware, very interesting discoveries have already been made, notably that of the underground rivers of Bramabiau (Gard) and of Padirac (Lot). Among those who have joined the Société de Spéléologie are several well-known men of science. All information is to be obtained of M. Martel, 8 rue Ménars, Paris.

THE idea of holding International Mathematical Congresses is crystallising into shape. Prof. Vassilief, of Kazan, has suggested an assembly of mathematicians in 1896, in order to definitely decide the organisation of such congresses. The matter was pushed a little further at the Vienna meeting of the Deutsche Mathematiker Vereinigung, in September last, when it was unanimously resolved that the committee of the Mathematical Union should take part in framing the necessary arrangements; and the Mathematical section of the French Association for the Advancement of Science have also expressed their support of the scheme. A circular now informs us that the Editors of the *Intermédiare* will be glad to receive the names of mathematicians who are in favour of international meetings of the kind suggested. M. C. A. Laisant's address is 162 Avenue Victor-Hugo, Paris; and that of M. E. Lemoine, 5 rue Littré.

THE *Johns Hopkins University Circular* states that it is proposed to collect the physiological papers and addresses of Prof. Martin, and publish them as one of the memoirs of the Biological Laboratory of the Johns Hopkins University. This plan has been adopted in response to suggestions from a number of his former pupils, that the long and valuable services of Prof. Martin to the University, and his brilliant contributions to American physiology and biology, should be commemorated by a memorial of some kind. After consultation with a number of his friends, it has been decided that the most appropriate form of memorial will be the publication in a handsome volume of his scientific papers and addresses. It is hoped to raise a fund among his friends sufficiently large to meet the cost of an edition of about 300 copies. One copy will be sent to each person or institution subscribing ten dollars, and, if desired, an extra copy for every additional ten dollars subscribed. As the work will be placed at once in the hands of the printer, it is requested that subscriptions be sent promptly to Prof. W. H. Howell, Johns Hopkins University, Baltimore.

THERE are often hidden meanings in the humorous answers given by schoolboys in the examination room. From a collection of such answers in the *University Correspondent*, we cull a few authenticated specimens. "Parallel straight lines," said one boy, "are those which meet at the far end of infinity." And another sagely remarked that "Things which are impossible are equal to one another." The boy who wrote "A point is that which will not appear any bigger, even if you get a magnifying glass," would have no difficulty in understanding that a star, being but a lucid point, cannot be magnified. Every examiner is familiar with the non-committal answers frequently received, and with which may be classified the cautious statement that "Two straight lines cannot enclose a space, unless they are crooked." But even these words of wisdom are eclipsed by the definitions of kinetic and of potential energy once received. "Kinetic energy," ran the definitions, "is the power of doing work. Potential energy is the power of doing without work." This truth, which has a monetary application, is well worth adding to our contemporary's collection.

A SWARM of bees in December is remarkable enough to be put on record. According to a Long Sutton (Lincolnshire) correspondent of the *Daily Telegraph*, a few days ago there was a swarm of bees on a farm at Spalding, Sutton Crosses.

THOUGH the present age is not very favourable to the development of pure science, applied science flourishes like a green bay tree. An instance of this growth is afforded by a note from the Institution of Civil Engineers, with reference to the present membership. The Institution, which was established in January 1818, and incorporated by Royal Charter in June 1878, for the general advancement of Mechanical Science, now consists of as many as 6660 members.

IMMEDIATELY following the recent very high barometric pressure, which reached 30·93 inches on the west coast of Ireland on December 27, a large disturbance advanced over the northern parts of our islands from the Atlantic, and during the night of the 28th, destructive gales from W. and N.W. were experienced over the whole country, accompanied by snow, thunder, and lightning. In some districts the storms lasted for several days, and were followed by sharp frosts, generally. At Greenwich a wind pressure of 28 lb. on the square foot was registered on Saturday morning, this pressure being one pound less than in the severe storm of the previous week.

IN *Naturwissenschaftlich Wochenschrift* for December 9, Dr. C. Hess discusses the hailstorms of Switzerland for the years 1883–1893, on the basis of the observations regularly published by the Meteorological Office at Zürich. He finds that hail is more frequent in the valleys than on the mountains, the latter at times transforming the hail into sleet, or rain. Near marshes, and in the valleys of the lakes, hail occurs more frequently than over wooded country, while the river valleys which lie in the direction of the paths of the thunderstorms favour the formation of hail. On passing over a cultivated district or a hilly forest, there is, however, a tendency to a decrease in the intensity, and, at times, an entire cessation of the hailstorms.

THE prize offered by the Hon. Ralph Abercromby for the best essay on "Southerly Bursters" (NATURE, vol. xlviii. p. 77) has been awarded by the Royal Society, N.S.W., to H. A. Hunt, of the Sydney Observatory, and the paper has been published in vol. xxviii. of the *Journal* of the Society. The essay, which extends to forty-seven large octavo pages, and is illustrated by four photographic plates, contains a short note on "bursters" in New South Wales and other colonies, and gives tabular statements of all that have taken place at Sydney between September 1863 and March 1894. These storms occur very suddenly, and mostly between November and February; a fresh north-easterly wind may change in ten minutes to a gale from the south, doing much damage to vessels that may be unprepared. The storms are always accompanied or preceded with great electrical excitement, and cause a considerable drop in the temperature. The wind velocity used to reach from 60 to 80 miles an hour, and on one occasion attained the rate of over 150 miles in the hour, in a gust. Latterly, however, the wind seldom exceeds 50 miles, and generally ranges between 20 and 40 miles an hour. This result possibly arises either from obstruction to atmospheric disturbance by increased number of buildings, or from less absorption or radiation of heat, owing to greater cultivation of the land. The average annual number of storms is thirty-two. The investigation is the result of much patient research, facilitated by reference to unpublished documents to which access was allowed by the Government Astronomer of the Sydney Observatory.

WE are informed that one of the points in the Report of the Upsala meeting of the International Meteorological Committee, contributed by Mr. Lawrence Rotch to the *American Meteorological Journal*, and reprinted in NATURE of December 20, is misleading. It was stated that "a proposition of the Russian Admiral Makaroff, on the necessity of an international convention to arrange for the discussion of the data contained in ships' logs, was not approved." This is erroneous, for we understand that Admiral Makaroff did not ask the Committee to express an opinion upon his scheme, so the subject was not discussed at all.

THE significant name "*Pithecanthropus erectus*" is proposed by Dr. Eug. Dubois, of the Netherland-Indies Army Service, for some fossil remains recently discovered in the andesitic tuffs of Java, as indicating the former existence in that island of an intermediate form between man and the anthropoid apes. The bones, which consist of the upper part of a skull, a very perfect femur, and an upper molar tooth, are elaborately described and figured in a quarto memoir recently published at Batavia.

THE announcement that the Surinam water-toads, recently received by the Zoological Society, have commenced to show the curious phenomena of their reproduction, in the Reptile House, has created much interest amongst zoologists. There can be no doubt that one of these living specimens now carries a layer of ova placed in cells in the skin of its back, and that about eighteen days after the deposition of the ova, young tadpoles were visible in some of the cells. Thus the extraordinary facts recorded by Madame Merian, concerning the reproduction of this abnormal Batrachian in the latter part of the last century, and not, we believe, subsequently noticed, have been already partially verified.

DR. ANTON REICHENOW, of the Royal Zoological Museum of Berlin, has just completed a memoir on the birds of German East Africa, which will form a portion of the third volume of Stuhlmann's work, "Mit Emin Pascha in's Herz von Afrika." The memoir gives an account of 728 species of birds which have been recorded up to the present time, by German naturalists and other explorers, as met with within the limits of the German Protectorate. The remaining portions of the same volume, which are in progress under the editorship of Dr. Möbius, will complete the account of the vertebrates. The fourth volume, under the same editorship, will be devoted to the invertebrates, and the fifth, edited by Dr. Engler, to the botany of the German East-African Protectorate. Vol. vi. will give an account of the geography and meteorology, and vol. vii. of the geology and mineralogy of the same country. It may be asked how long we shall have to wait for a similarly complete account of British East Africa?

THE "Zoological Record" for 1893, which has just been published by Messrs. Gurney and Jackson, for the Zoological Society of London, has appeared rather later than usual. Its bulk shows us at once that the quantity of work accomplished by zoologists in 1893 is not inferior in amount to that of the immediately preceding years. Some of the recorders, we may be allowed to point out to Dr. Sharp, commence their "Records" with an interesting account of the principal events that have taken place in their special branches of the subject during the year of record. Others altogether neglect this very desirable piece of information. It would be well to insist that a page or two of introduction, containing matter of this description, for the general information of zoologists, should be prefaced to every section of the "Record." Many readers who do not care to study the special portion, would like to get a general notion of what has been going on.

AN exhaustive bacteriological investigation of the Altona water-supply has been recently published by Dr. Reinsch. Although the results obtained are not specially novel, yet they are of importance as confirming the researches of other investigators. It is pointed out that whilst the layer of slime which forms on the surface of sand-filters plays an important part in the retention of microbes, yet another factor must be most carefully watched if a satisfactory filtrate is to be obtained. This factor is the depth of the column of fine sand through which the water is made to pass. It was first called attention to by Dr. Percy Frankland in 1886, in the course of his examinations of the London water supply; and since that time investigations made at Zurich and elsewhere, have shown that it is not advisable to reduce the layer of sand below 30 c.m. Reinsch states that it should never be less than from 40–60 c.m. high. This investigator also states that to encourage the formation of surface-slime, the filters, after the water is first run on, should be left undisturbed for twelve hours, and that the neglect of this simple precaution exercised an important influence on the filtrate.

SOME vexed points in the developmental history of medusæ have been attacked in a masterly manner by Miss (?) Ida H. Hyde, who publishes a paper on this subject in the *Zeitschrift f. wiss. Zoologie* (Bd. lviii. iv.). The material for her investigations consisted of embryos of three different species of *Aurelia* and *Cyanea*. The formation of the endoderm is shown to vary considerably in different species and even in the same species. In *A. marginalis* the endoderm is formed by multipolar delamination, in *C. arctica* by delamination at the pole of the blastopore. In *A. flavidula* the endoderm sometimes arises by embolic gastrulation, with or without the participation of a few immigrant or delaminated cells, but in other cases arises almost exclusively from immigrant and delaminated cells, the invaginated element being relatively insignificant. These differences of origin in the same species seem to be determined by local conditions of temperature and salinity of the water. The author regards multipolar delamination as the most primitive of the various processes by which the endodermal digestive chamber is brought about. The development of the *Scyphula* larva is then traced, and the author is able to confirm Goette's account in all essential points. There is a true stomadæum, and the invaginated ectoderm also takes part in the formation of the four septa and of the gastral filaments of the *Scyphostoma*. The points of affinity which have been raised between the Scyphomedusæ and the Anthozoa thus acquire new and substantial support from Miss (?) Hyde's researches.

A NEW periodical, *Archiv für Entwickelungsmechanik der Organismen* (Leipzig: Engelmann), of which the first number lies before us, is intended by the editor, Dr. W. Roux, to provide a medium for the publication of researches upon the causes of the phenomena of organic development, as distinct from the mere normal order of the phenomena themselves. The journal is to furnish an organ for that branch of biology which has been variously termed the "mechanics of development" and "causal or experimental morphology." In the hands of Roux, Driesch, Hertwig, Chabry, Wilson, and others, the methods of this school, which are above all things experimental, have been applied to various problems in development with much success and with the most interesting results. It is therefore to be hoped that the publication of a journal specially devoted to experimental morphology will lead to a considerable increase in the number of investigations in this promising field. In the present number the editor gives an introduction on the objects, methods, and scope of the branch of biology the new *Archiv* represents, and a number of interesting researches are published on the "cytotropism" of isolated blastomeres, on compensatory hypertrophy of organs and regeneration, and on the origin of the forms of joints.

THE young cocoa-trees in one part of the island of Jamaica are suffering from the attacks of a caterpillar. A correspondent calls our attention to a letter in the *Jamaica Gleaner*, in which Mr. W. Fawcett, the Director of Public Gardens and Plantations, regrets that the museum is at present without the services of a curator, who might be able to give some information as to the best means of dealing with the caterpillars, and the remedy he suggests for keeping down the plague is by hand-picking. In this connection, a summary of a report on a plague of caterpillars at Hong Kong, in the current *Kew Bulletin*, is of interest. These caterpillars appeared on pine-trees, and belonged to a large moth (*Metanastria punctata*, Walker). The trees attacked were those of *Pinus sinensis*, Lamb, very largely planted in the island for re-foresting purposes. Active steps were taken by the Government to destroy the pests, by establishing stations where the caterpillars could be received and paid for by weight. The caterpillars were caught by shaking the trees and picking them off the ground. From the report summarised in the *Kew Bulletin*, it appears that the plague lasted two months. The quantity of caterpillars collected weighed nearly thirty-six tons, and a large number of cocoons were also destroyed. Altogether it is estimated that thirty-five million insects were destroyed. Mr. W. J. Tutcher, who drew up the report, says that the methods employed for the extirpation of the scourge were decidedly successful; so that if similar measures are promptly taken at Jamaica, the caterpillars may be kept under.

IN measuring the volume of a solid by immersion in a liquid, it is usual, after withdrawing the solid, to find what volume of liquid is required to re-establish the former level. The well-known difficulty of identifying the former level is overcome by Sgr. Guglielmo in a manner described in the current *Atti dei Lincei*. He grinds the edges of a beaker, and mounts inside it a pointer of glass or platinum so that its fine point lies just in the plane of the edge. This is accomplished while the mounting cement is still soft, by inverting the beaker on a plane surface, and thus pressing the point into its place. A burette with an india-rubber tube enables the observer to add or withdraw a known volume of water. In order to measure the volume of a solid, the plane horizontal edge of the beaker is lightly spread with grease or paraffin, and the beaker is filled up until the unevenness in the liquid surface produced by the pointer has just disappeared. A volume of water larger than the solid is then withdrawn, and the latter is immersed. The liquid is then brought up to the point again, and the difference of level in the burette is the volume required. The reflection of the bar of a window or other straight line in the liquid is useful for discovering any deformation of the surface. If the pointer should not be easily wetted, a few drops of soap solution are recommended, or the substitution of petroleum for water.

The comparison of condensers of small capacity and the measurement of the specific inductive capacity of liquids is of considerable importance. An interesting paper on this subject was read by Prof. Nernst, of Göttingen, before the German Electro-Chemical Society (see also *Zeitschrift für Physikalische Chemie*, vol. xiv. p. 622), in which he describes a method for measuring the specific inductive capacity and specific resistance of liquids. The author uses a modification of De Santy's method, in which a telephone is used in place of a galvanometer, alternating currents supplied by a small induction coil being used. The resistances employed in the bridge must necessarily be non-inductive, and also, since the capacities to be compared are very small, of practically evanescent electrostatic capacity. Hence the author uses liquid resistances contained in fine capillary tubes, the electrode at one end consisting of a fine platinum wire, which can be moved along the bore of the tube by means of a micrometer screw, and thus the resistance of the liquid column be varied at pleasure. An air condenser is used as a standard with which to compare the condenser containing the liquid under observation, and when this liquid is not a perfect insulator the telephone cannot be brought to complete silence by altering the resistances. To overcome this difficulty the author places a high resistance shunt on the air condenser, which is adjusted so that complete silence is obtained.

A system of two pendulums joined by an elastic thread has been studied by M. Lucien de la Rive, and the results of his experiments are given in the *Journal de Physique*. The masses and the lengths of the two pendulums were equal, and the elastic threads consisted of pure unvulcanised caoutchouc, long enough to make the amount of stretching small in comparison with their length. It was found that there was a periodical transmission of energy from one pendulum to another. On starting one pendulum, and arranging the thread so that it always remained stretched, the other pendulum started swinging with increasing amplitude, until the first was for an instant reduced to rest. After that the second pendulum was gradually reduced to its minimum, which did not, however, attain zero, while the other reached its maximum. This transmission of energy exhibited a fixed period, which could be derived from the ordinary period of each pendulum by multiplying with a number proportional to the length, and inversely proportional to the sectional area of the thread. In the end, the pendulums tend to oscillate like a rigid system, with a constant tension of thread. After ten or twelve oscillations, the alternation of periods is hardly perceptible. When one pendulum only was attached to a fixed point by an elastic thread, the decrement was observed in order to determine the internal friction of the thread. This internal friction gives rise to an elevation of temperature which has been exhibited by Warburg, who placed india-rubber tubes round glass-tubes containing sounding columns of air, and observed the rise of temperature in the caoutchouc. It shows an analogy to that in wires due to electric currents.

On October 27, as we have recorded in a previous number (p. 18), a disastrous earthquake occurred in Argentina. The exact time is as yet unknown, and it is therefore uncertain whether any connection exists between this earthquake and a remarkable series of pulsations that were registered on the same day in several European observatories. At Rome, a very slight and comparatively rapid movement of the great seismometrograph (length, 16m., mass, 200 kg.) commenced at 9h. 7m. 35s., p.m. (Greenwich mean time). This lasted until 9h. 40m., when the slow pulsations began to be visible. The first maximum occurred at 9h. 49m. 50s., and the principal one at 9h. 55m. 40s. The amplitude then rapidly diminished, with occasional maxima, the disturbance lasting until about 11 p.m. Pulsations were also recorded at about the same time at the geodynamic observatories of Siena, Ischia, Pavia, and Rocca di Papa. The period of the complete oscillations at the time of their maximum amplitude was found to be 16·7 seconds at Rome, and about 18 seconds at Siena and Rocca di Papa. In the south of Russia, at Charkow and Nicolaiew, horizontal pendulums were strongly disturbed. At the former place, the movement began at 9h. 8m. 36s., p.m., and, for more than an hour, was so great that all traces of the photographic curve disappeared. The large oscillations lasted until 11h. 9m. 48s., and the small ones until 0h. 10m. 54s. a.m., of the following day. At Nicolaiew, the disturbance was first perceptible at 9h. 12m. 6s., p.m., and the curve disappeared almost completely between 9h. 24m. 6s. and 10h. 2m. 6s., the pendulum continuing in oscillation until 0h. 37m. 6s., a.m., of the next day. The magnetographs at Utrecht and Wilhelmshaven also showed traces of the pulsations, at the former place beginning at 9h. 45m. 28s., and reaching a maximum at 9h. 56m. 28s., at the latter beginning at 9h. 55m. 25s. and ending at 10h. 11m. 55s. No disturbances are perceptible on the magnetograms at Lisbon, Perpignan, Paris, Kew, Greenwich, Stonyhurst, Vienna, and St. Petersburg (*Boll. Meteor.*, Suppl. 112).

The last issue of *Studies from the Yale Psychological Laboratory* contains an interesting record of Dr. Gilbert's researches on the mental and physical development of school-children between the ages of six and seventeen years. On the physical side, statistics are given of increase in (*a*) weight, (*b*) height, and (*c*) lung-capacity. On the psychological side, there are observations on the development of the power of perception and discrimination as exercised upon (*a*) weights poised in the hand, (*b*) colour-differences in a series of shades of red, and (*c*) time-intervals. To these are added observations on the "force of suggestion," in which, by means of a series of loaded blocks (1) of different sizes but the same weight, and (2) of different sizes and different weights (the two being nowise correlated), it is shown that visual perception of size very markedly affects weight-discriminations. Reaction time, with and without discrimination and choice, was tested; and observations were made on the influence of fatigue on "voluntary motor ability" as measured by the rapidity of tapping with the key of a specially devised piece of apparatus. In all cases the results, both for boys and girls, are summarised in curves on the graphic method. One of the interesting features to be noticed in these curves is the influence of puberty on mental development, there being a marked depression in the curves at the age of from thirteen to fourteen years. Another noteworthy piece of work, recorded in the same number, is that by Dr. Scripture and Mr. H. F. Smith, which deals with the highest audible tones. The general result is that the pitch of the highest note varies directly and almost proportionally with the intensity. It is also shown that the limit of audibility is much higher when reached by descent from more rapid inaudible vibrations, *i.e.* proceding from silence to sound, than it is when reached by ascending from less rapid audible vibrations, *i.e.* proceding from sound to silence.

THE ninth part of "The Natural History of Plants"—the English edition of Prof. Kerner's admirable "Pflanzenleben"—has been published by Messrs. Blackie and Son.

MESSRS. A. AND C. BLACK have published the hird part of "A Dictionary of Birds," by Prof. Alfred Newton, F.R.S. The part extends from "Moa" to "Sheathbill." We propose to review the complete work when the fourth (and last) part has been issued.

"WEBSTER'S PRACTICAL FORESTRY," published by Messrs. Rider and Son, has reached a second edition. We reviewed the work when it first appeared (NATURE, vol. xlix. p. 526), and it is only necessary to add to the remarks then made that the author has enlarged the volume, thus increasing its value as a practical and popular handbook on the rearing and growth of trees.

THE second volume of Mr. Boulenger's "Catalogue of the Snakes in the British Museum," which has just been issued, concludes the account of the Aglyphodont Colubrine Snakes, and gives descriptions of 427 species, which are represented in the collection by 2528 specimens. We understand that the MS. of the third and concluding volume of this important work is nearly ready for press.

THE December number of the *Journal* of the Royal Microscopical Society has just been received. It contains a paper by Mr. F. Chapman, on the Foraminifera of the Gault of Folkestone (part vii.), and a description of a simple method of measuring the refractive indices of mounting and immersion media, by Mr. E. M. Nelson. The invaluable summary of current researches in zoology, botany, microscopy, &c., takes up the chief part of the journal.

WE note the commencement of vol. xxx. of the meteorological publications of the Manila Observatory. The *Bulletin* for the year 1894 is in a large quarto form, which is much more convenient in size than its predecessors. In addition to a good summary of the weather over the Philippine Islands, the work contains hourly observations for Manila, and observations taken twice daily at a number of secondary stations, together with rainfall and other maps.

MESSRS. WHITTAKER AND CO. will issue the first number of a new science weekly on January 5. The new journal will embody the combined features of *The Technical World* and *Science and Art*, two periodicals which have hitherto appeared as separate organs. It will appeal to all persons interested in the progress of art, science, and technology from an educational point of view. In addition to current news, the journal will contain articles in all the departments of pure and applied science and art.

A FINE geological map of Alabama, drawn on a scale of an inch to ten miles, has been prepared and issued by the Geological Survey of that State. The map is accompanied by a very useful explanatory chart, showing, in four parallel columns, (1) the names, synonyms, classification, and common fossils of the formations; (2) the thickness, lithological and topographical characters, area and distribution; (3) useful products; (4) soils, characteristic timber growth, agricultural features. By means of this chart and the coloured map, the geological record of Alabama can be read by any one.

WE have received from Dr. A. von Danckelman, an excerpt paper from vol. vii. of "Mittheilungen aus den deutschen Schutzgebieten," containing some valuable meteorological observations made by Dr. Steinbach, during the year 1893, at Jaluit, an island in the North Pacific. The station is situated in 5° 55′ N. lat. and 169° 40′ E. long., and is only five feet above mean sea-level. A Richard barograph was sent out by the Deutsche Seewarte in 1892, but the vessel was wrecked on approaching the island; another was supplied, and records were commenced on January 1 last. The observations for 1893 show that the air temperature is exceedingly uniform, the yearly range only amounting to 22°; the absolute maximum was 92°·8 in November, and 70°·7 in September. Cloud is very prevalent, there only being six clear days during the whole year. Rain falls almost daily, there being 343 wet days during 1893, the total fall being 182 inches; the greatest fall in twenty-four hours was 4·5 inches. Thunderstorms are not very frequent; there were only thirty-two in the year in question, but it is noteworthy that the majority occur in the forenoon, to an extent which has, we believe, not been observed at any other station.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mr. J. Hussey; two Red-eared Bulbuls (*Pycnonotus jocosus*) from India, presented by Brigade-Surgeon Lieut.-Colonel E. F. Drake Brockman; a Cape Bucephalus (*Bucephalus capensis*), a Rhomb-marked Snake (*Psammophylax rhombeatus*) from South Africa, presented by Mr. J. E. Matcham.

OUR ASTRONOMICAL COLUMN.

A NEW SHORT PERIOD VARIABLE.—The possible variability of *d* Serpentis was suggested some time ago by the Potsdam photometric work, and the variation has now been confirmed by Mr. Yendell (*Astronomical Journal*, No. 331). Fifty observations made by him between August 5 and November 4 of last year indicate a variation from magnitude 5·0 to 5·7 in a period of not far from 8·7 days. The form of the light-curve appears to resemble that of β Lyræ, though this is not yet certainly established. There appear to be two maxima, one at 2·2 days, and the other at 6·2 days from the principal minimum, while there is a secondary minimum of about magnitude 5·5 at 4·3 days from principal minimum. Mr. Yendell suggests the provisional elements

1894, August 7·6 (G.M.T.) + 8d.·7 E.

The new variable is chiefly of interest in the probable resemblance of its light-curve to that of β Lyræ. Notwithstanding the very detailed investigations of the spectrum changes in the latter variable, which have been recently made at Harvard, Potsdam, Pulkowa, Stonyhurst, and Kensington, the cause of the variability is by no means completely understood. In this case the spectrum is a complicated one, consisting of bright lines as well as dark ones, and the Kensington photographs have shown that there are two distinct sets of the latter. According to the Draper catalogue, however, the spectrum of *d* Piscium is of the Sirian type, and no mention is made of bright lines. It may be that a complete study of the simpler spectrum of this star will throw some light on the origin of the variability in β Lyræ, and possibly also on the causes which produce other kinds of continuous variability in short periods.

The position of the star for 1900 is

R.A. 18h. 22m., Decl. + 0° 8′.

DOPPLER'S PRINCIPLE.—The verification of Doppler's principle has hitherto depended upon comparisons of the spectroscopically measured velocities in the line of sight of Venus, and of the sun's limb with their known velocities, and upon the consistency of the measured velocities of stars when due allowance is made for the varying effect of the earth's movement. Dr. Belopolsky, however, has recently suggested a method (*Astr. Nach.* No. 3267) of demonstrating the principle by a laboratory experiment. Imagine two cylinders with axes parallel, on which are arranged vertically two sets of small mirrors, *a*, *b*, *c* . . ., *m*, *n*, *o* . . . The mirrors are inclined so that a ray of light falling on *a* is reflected to *m*, back again to *b*, then to *n*, and so on, finally being directed to the slit of the spectroscope. If now the cylinders be set in rapid rotation, in opposite directions, the effects of the mirrors will be to accelerate or retard the velocity of the ray of light according to the directions of movement. Figures are given which indicate that measurable displacements may be obtained by employing cylinders of from 0·25 to 0·7 m. diameter, with ten or twenty mirrors, making from eighty to twenty revolutions per second. With cylinders half a metre in diameter, making eighty revolutions per second, and having twenty mirrors, the equivalent of a velocity of five kilometres per second in the line of sight is obtained, and with modern instruments there would be no difficulty in observing the effects of such a movement. It is pointed out that dynamos already make from seventy to eighty revolutions per second, and if sufficient care be taken in the construction of the cylinders, the experiment does not seem to present insuperable difficulties.

"THE ASTROPHYSICAL JOURNAL." This is the title under which *Astronomy and Astro-Physics* will appear in future. The University of Chicago has purchased that journal, and arrangements have been made to carry it on under the editorship of Profs. Hale and Keeler, assisted by Profs. Ames, Campbell, Crew, Frost, and Wadsworth, and a number of associate editors, five of whom represent Germany, Great Britain, France, Italy, and Sweden. The scope of the new publication will be quite as broad as that of *Astronomy and Astro-Physics*, for all problems and investigations of modern physical astronomy will be dealt with. The journal will, in fact, represent the common ground of physics and astronomy, and it should therefore be appreciated by the physicist as much as by the astronomer. Workers in astronomical physics should be gratified that their science has progressed sufficiently to need a special organ to be devoted to its interests. *Popular Astronomy* will be continued as heretofore, and will appeal to all amateurs, teachers and students of astronomy, and others interested in celestial science. This journal will be practically the old *Sidereal Messenger*, and the *Astrophysical Journal* will be the realisation of Prof. Hale's original plan of a periodical for workers in the domain of the new astronomy.

ELLIPTICAL ORBITS.—A little pamphlet on elliptical orbits, by Mr. H. Larkin, has been published by Mr. Fisher Unwin. If it should induce any student of astronomy to construct for himself the curves in which the apparent orbit of a binary star, as we see it, may be resolved, it will serve one useful purpose, and probably the only one. For it is to be hoped that the same student will not embrace the theory of formation of binary stars as given here, wherein they are made to result from the explosion of one larger star. There are many other strange things taught, of which Newton never dreamed, and which no one capable of reading Newton would ever have stated. Perhaps the most singular is the suggestion of "precarious equilibrium" that would accompany motion in a circular orbit. "Precarious equilibrium" is a curious term, but the context seems to suggest that some catastrophe or disaster would result from such a condition. The author does not seem to have realised that there is no sudden and violent change between an ellipse of small eccentricity and a circle, and that in the solar system there are instances in which the eccentricity (if existing) is so slight that the motion can be conveniently considered as circular.

FORESTRY IN NATAL.[1]

NATAL lies between latitude 28° and 31° S. The climate of the coast is almost tropical, owing to a warm current from the equator. Mangrove trees grow along the coast, and sugar-cane and tropical Indian fruit trees are cultivated there. The land ascends rapidly inland, and the capital, Pietermaritzburg—or Maritzburg, as it is usually called, at fifty miles from the coast—is at 2275 feet above sea-level, and possesses an appreciably mild climate.

The colony is bordered on the west by the Kathlamba or Drakensberg, a mountain chain attaining altitudes which exceed 9600 feet, and separating Natal from the Transvaal, the Orange Free State, and Basuto-land. These mountains form the eastern boundary of the high South African plateau, which is drained by the Orange River and its tributaries.

Natal is scantily populated, containing 18,755 square miles, with 532,000 inhabitants, of whom 38,000 only are Europeans. Most of the latter are English who came by sea and founded Port Durban, but a few are descended from the Dutch Boers who came from the west in 1838–42 and founded Maritzburg. Natal has been an English colony since 1843, when the territory only included 3000 native inhabitants, but their numbers rose rapidly to 100,000 in 1845, and to 400,000 in 1883. They are mostly Zulus in the north, and Kaffirs in the south of the colony.

Much greater progress could have been made in Natal, in trade, agriculture, and manufactures, if it had been connected by roads and railways with the Transvaal and Orange States. The Cape railway, 650 miles long, from Cape Town to Kimberley, with express trains doing the distance in thirty-six hours, has long been constructed, and in 1893 this railway was extended to the Transvaal gold mines at Johannesberg.

In 1880 a railway was constructed from Durban to Maritzburg, but only recently has it been pushed further inland, and it now reaches the confines of the colony. Its further extension to Johannesburg is most important for the future prosperity of Natal. About one and a half years ago a railway was made from Ladysmith in Natal to Harrismith in the Orange State. Natal is at present short of funds, and this may partly explain why, having made a good start in forest conservancy, the Colonial Government has not had the resolution to persevere in it.

The Cape Colony has had for some time a good forest administration which was organised by a French forest officer, Count Vasselot de Regné, Conservator of Forests in Algiers, and Mr. D. E. Hutchins is now Chief Conservator of Forests at Cape Town. He was trained at Nancy for the Indian forest service, and left it for service at the Cape in 1883. Mr. Fourcade, of the Cape forest service, was employed in Natal for nine months in 1889, and has written a very valuable paper on the Natal forests, but he declined to quit the Cape service permanently for that of Natal, and was succeeded in 1891 as chief forest officer there by Mr. Schöpflin, a Baden forest officer.

The work he undertook of organising a forest department in Natal was full of difficulty, especially as the forest revenues were not expected to cover the expenditure for a number of years. Irrespectively of the continual clearance of forests for the extension of agriculture, forest fires, unregulated grazing, and wasteful timber felling have so exhausted the Natal forests that the areas still covered with brushwood and forest are widely scattered over the country, and only a small percentage of them is still State property.

From the coast to altitudes of about 975 feet, with an average annual temperature of 67°–71°, the forest consists of numerous species belonging to the tropical flora. The woods are not more than 30–60 feet high, but something might be made of them, as several species yield valuable timber. Unfortunately nearly all the coast forests are now private property.

In a central zone ranging in altitude between 980 and 3450 feet with an average annual temperature of 59°–67° F., extensive tracts are covered with so-called mimosa scrub, formed of several species of *Acacia*; these woods are very thinly stocked, and contain a tall grass undergrowth. The acacias bear plenty of seed, and young growth exists, but is continually being destroyed by the annual grass fires. If only protection could be afforded to these forests against fire, as has been done for the last thirty years in British India, they could be worked profitably with short rotations—twenty-four years, according to Mr. Fourcade; it is, however, probable that most of this area will be cleared for agriculture.

The present area of the coast and acacia forests is estimated at 196,000 acres of State forest, and 1,645,000 acres in private hands.

In the higher zone, from 3450 feet up to 9600 feet, with a temperate climate, and an average annual temperature of 52°–59°, the most valuable forests are situated, but they are

[1] Translation of a paper by Sir Dietrich Brandis, K.C.I.E., F.R.S., in the *Forst und Jagd Zeitung*.

scattered over a difficult mountainous region. Of these forests, the State possesses 54,000 acres, and 27,000 acres are in a territory assigned to the indigenous inhabitants of the country. The Government has decided that in the mountains the action of the Forest Department will be restricted to the State forests. They contain many species; *Podocarpus Thunbergii* and *P. elongata*, both known as yellow-wood, are the commonest, and their wood resembles that of the European spruce. At present the great cost of transport prevents the profitable working of yellow-wood. Amongst the remaining species, the two most valuable trees are stink-wood (*Ocotea bullata*), so named on account of the bad odour of freshly-sawn wood, an evergreen lauraceous species with a beautiful brown heart-wood, which is hard and tough; and sneeze-wood, *Pteroxylon utile*, an ally of the horse-chestnut. These woods are also highly esteemed in the Cape Colony, especially for cart and wagon making, and can be worked at a profit even from these remote mountain forests. Unfortunately these two species are only found here and there in the forests, and there is no large supply of them.

In the year 1891-92, the sale of wood by the Natal Forest Department yielded £725, while the expenditure was £1942, partly for establishment and partly for the survey of the forests. Owing to the small area of forests available, and the remote position of the State forests, Mr. Fourcade strongly recommended that plantations should be started near the towns and railways. Past experience with the blue gum (*Eucalyptus globulus*) is favourable for the success of this tree in Natal. At Arambi, near Ootacamund in the Nilgeri Hills in India, this tree attains a height of 107 feet in nineteen years, and yields 8696 cubic feet per acre. This enormous production of 457 cubic feet per acre annually was attained in latitude 11° N. at an altitude of 7426 feet above sea-level.

In the higher latitude of Natal, a similar climate to that of Arambi is found at 2275 feet above sea-level, and, according to Mr. Fourcade, mixtures of *Eucalyptus globulus*, *longifolia* and *rostrata* give an even higher yield near Maritzburg than at Arambi. Mr. Schöpflin doubts whether this will be the case; but, at any rate, the gum-trees will give a large yield, and if the wood were only fit for fuel a considerable pecuniary return would be obtained. Several of the gum-trees, however, yield splendid timber, and especially *E. rostrata*, the red gum of Southern Australia.

Timber imports into Natal average in value £180,000 a year, so that, as the indigenous forests are small, much subdivided, and unfavourably situated, the State is clearly called upon to plant up a sufficient area of the State lands. Mr. Fourcade states that the land necessary for these plantations can now be purchased cheaply, and Mr. Schöpflin commenced planting operations. This useful measure is now abandoned, owing to want of funds, and the plants in the State nurseries will be sold.

Besides *Eucalypti*, several Australian acacias succeed admirably in Natal, especially *A. decurrens* and *mollissima*; their bark is rich in tannin, and a plantation of 1200–1500 acres of these trees has been started by a private company. Near the neighbouring Transvaal gold-fields, Australian trees are being planted on a large scale to supply mine-props.

The length of rails in Natal is about 625 miles, and the mountain forests will yield a portion of the necessary railway sleepers. Yellow-wood must be kyanised, as has been done in the Cape Colony, and kyanising works can easily be established in Natal, and wood from gum-tree plantations ought to supply the balance of the sleepers required.

It is evident that Natal cannot possibly prosper without a Forest Department, and the colony will have cause to regret having abandoned the attempt to form one, after such an excellent beginning has been made. The Government wished to retain Mr. Schöpflin's services up to March 31, 1894, but would not undertake to employ him after that date. Under these circumstances, he was obliged to resign his appointment last September, in order to return to the Baden Forest Service.

W. R. FISHER.

THE FERTILISATION OF "LORANTHUS KRAUSSIANUS" AND "L. DREGEI."

THE parasite *Loranthus Kraussianus* grows on the coast here on the tree *Chætacme Meyeri*, and as three of these trees grow within a short distance of my house, I have this season had a good opportunity of observing the rather curious mode of its fertilisation. In the flower bud the corolla segments adhere along their whole length, forming an upright cylinder, of about an inch long, of red and white, thus getting the not inappropriate colonial name of "lighted candles." The flowers grow in close umbels, so close together as to give quite a reddish tinge to the host tree. After a little time five slits appear about half-way up the upright cylindrical corolla, and these slits are about one quarter the length of the cylinder. The anthers occupy *almost* the extreme tip of the cylinder, and are pressed against each other by the closed tube of the corolla (the cylinder aforesaid), the actual tip being occupied by the capitate stigma. If a needle be inserted into one of the slits of the corolla with a downward movement, as if to seek the nectar at the base, it causes the tube to split with some force, and at the same time the anthers are quickly and forcibly released from their pressure one against the other, and fly downwards violently, scattering practically all the pollen they contain by the one movement; and at the same time the stigma, from being upright, springs to an angle of, say, 40 degrees on one side quite clear of the now split corolla tube. I found by microscopic observations of a number of stigmas just at this stage, that only in a small proportion of cases (I only found one) did any of the triangular pollen actually reach the stigma by the act of explosion, although the style was fairly thickly peppered. These flowers are constantly being visited by large numbers of the commonest coast sunbird (*Cinnyris olivaceous*), a very active and hard-working, though not very brightly coloured, member of the sun-birds. A little quiet watching will show the birds at these flowers splitting open flower after flower, and getting head and bill covered with pollen in moving about, undoubtedly fertilising the capitate receptive stigmas (in the receptive stage protruding free from the corolla tube) of other and older flowers. After seeing them thus at work, the question arose whether without their aid the bursting of the flower happened. The negative evidence was that although I had observed for many hours, I never saw a simple flower voluntarily explode; but to check this, I put a net-bag over a small branch containing, say, 80 to 100 healthy flowers. I found that when thus protected hardly a single flower got to a further stage than having the splits on the corolla tube ready for the outside aid of the sunbird to enable them to perform the next function, viz. explosion. Actually none exploded, and, as a consequence, not a single flower within the bag set seed. They seem to be quite sterile without outside help, the anthers dehisce, but at a level below the capitate stigma, and as the corolla tube is generally upright the pollen is lost even as a self-fertilising agent. After careful watching, I feel sure sunbirds are the only effective agents in the fertilisation of this plant. At first I never observed bees visiting it, and actually made a note to the effect that they did not do so; but at a later date they came in good numbers. They seemed simply to follow the birds, and take any nectar left by them in the exploded flowers, and very seldom, and then, I think, only by a happy chance themselves caused the explosion. I did not observe any other insect visitors, so that it would appear this plant is dependent on *Cinnyris*; and there is an element of irony in it, for from the berries of this plant the boys make bird-lime, and the energetic efforts of these lovely little birds are towards the perpetuation of the means by which they are often made captive. It would be interesting to know how far the different individuals of *Loranthus* on the one tree are in the position of independent individuals of terrestrial species (pollen from an *independent individual* being necessary for the most perfect results of cross-fertilisation), or whether the fact of having a common host approximates them in this respect to the position of one plant, and whether to get the best results of cross-fertilisation pollen should be brought not from flowers of a different individual on the same host, but from plants growing on a different tree altogether. To carry on the life-history of this plant, my friend Mr. Harry Millar, of Durban, informs me that the berries when ripe are taken by the little tinker bird (*Barbetula pusilla*), who eats the *covering* of the berry, and rejects the seeds and viscid matter around them, and to clear away the latter bangs the berry with his bill against a tree, where the seeds adhere with the viscid substance and germinate. I may say that Mr. Millar states that in shooting these birds, as specimens, he often finds the head and bill covered with pollen. I am informed that another sunbird (*Cinnyris Verreauxi*) visits this plant, but as it is of the same habits as *C. olivaceous*, the results of its visits, as far as the plant is concerned, would be the same.

Loranthus Dregei grows on the coastlands of Natal upon various hosts, most commonly perhaps upon the introduced Syringa, *Melia Azedarach*, and never, so far as I have observed, upon the tree (*Chætacme Meyerii*) infested by *L. Kraussianus*. While in the bud the petals form a cylindrical tube, and the anthers are pressed against the closed petals, the tips being just below the stigma. Subsequently slits appear on the still closed cylinder. My observations show that the plant is abundantly visited by *Cinnyris olivaceus* and *C. Verreauxi* and that both birds insert their long bills into the slit to get at nectar secreted at base of tube, exactly as in *L. Kraussianus*. In this species, however, instead of the anthers remaining still attached to the filaments when the flower jerks open, they are all broken sharp off, and fly off into space with great violence, parting with their pollen as they go. I find that although the pollen is thrown so far upwards as to reach the base of the stigma, the force appears so nicely adjusted that none actually reaches it, the great bulk of the cloud of pollen being thrown downwards so as to reach the head and beak of the visiting bird. Apparently after this dissemination of its pollen (and anthers) the flower still has attractions for the sunbirds, for I have seen them distinctly visiting the burst flowers, and this would of course be necessary if cross-fertilisation or, indeed, fertilisation of any kind took place. And on opening the burst flowers I found in most cases a quantity of nectar, so that probably secretion goes on after the flower is open and its anthers gone. I observed this plant repeatedly and at all hours of the day, and never saw it visited by a single insect of any kind; and although aware that negative evidence of this kind cannot be relied upon, my observations were so frequent that I feel sure any insect visitants, at all events diurnal visitors, must be exceedingly rare. I noticed one flowering upon *Acacia* sp. which was also in flower and visited by bees, but the bees took not the slightest notice of the flowers of the *L. Dregei*. I should judge from the length of the corolla tube, that if any insect visits this plant, it must be furnished with a long proboscis, for the flower tube from stigma to base is fully two inches long. As in *L. Kraussianus* the flowers need outside aid to burst at all, for I have watched them for long periods and in all kinds of weather, and never seen a single flower burst by its own volition. Although apparently entirely dependent on the sunbirds for its propagation, this mode of fertilisation must be very successful, for the plant is very common indeed. In addition to the fact of the flying pollen never reaching the stigma, and self-fertilisation being thus prevented, the flower seems to be proterandrous, for at a stage of development when a slight touch in the right place bursts the flower, the stigma seemed dry and unreceptive. After bursting, the stigma, instead of being in line with the corolla tube, inclines to one side, though not to such an extreme angle as in *L. Kraussianus*, and this deviation from the upright will help pollination to some extent. I have often watched the birds on these flowers bursting them, and each time causing quite a little cloud of pollen and anthers to fly, and the force is so great, the anthers are jerked to quite a considerable distance, and in no single instance did the force fail to detach the whole of them. It is a very pretty and interesting sight. In the case of this species, I believe it is absolutely dependent on the sunbirds for its sexual propagation.

Durban, Natal. MAURICE S. EVANS.

SCIENTIFIC INVESTIGATION IN CANADA.[1]

IN a Society formed to include as far as possible representatives of all branches of literature and of science, it appears to be most appropriate that the president for the time being should devote the address which it is his privilege to deliver, to some specific topic, or to the consideration of such matters of interest or importance as may lie particularly in his own line of work or thought. The literary, artistic, and political development of the country have already been dealt with. It may therefore be of some interest and service to give a very general and very brief review of what has been accomplished, and what remains to be accomplished in Canada, by various scientific agencies working in the investigation of the natural features, and towards the development of the natural resources, of the country.

Science is but another and a convenient name for organised knowledge, and as such it has entered so largely into every branch of human effort, that when, at the present time, any one attempts to pose as a "practical," in contradistinction to a scientific worker, he may be known to be a relic of the past age, in which much was done by rule of thumb and without any real knowledge of the principles involved. Neither can any division be made between what is sometimes called "practical" or "applied" science and science in general, for the knowledge must be gained before it can be applied, and it is scarcely yet possible to bar any avenue of research with a placard of "no thoroughfare," as an assurance that it cannot lead to any material useful end.

At the same time, there are certain directions in which investigation is very closely wedded to results of immediate and tangible value. But the line should not be too rigorously drawn, for should the investigator for a time stray into some by-path of research, because of his individual interest in his work, it is not improbable that he may return from his excursion with some unexpected discovery, which may prove to have important bearings on the problems of every-day life. Take, for example, the study of palæontology, which, relating as it does, to extinct forms of life, might appear to be a branch of science wholly removed from any practical object, however interesting it may be to disinter and to reconstruct these remarkable forms. But we all know that this study has become an indispensable one as an aid to the classification of the rock formations, and thus to the search for the useful minerals which some of these contain. This is more particularly the case, perhaps, in the instance of coal beds, which are usually confined in each region to some set of strata, which may be defined with precision only by the aid of the evidence afforded by fossil remains.

THE GEOLOGICAL SURVEY.

In the first united Parliament of Upper and Lower Canada, in 1841, the Natural History Society of Montreal and the Historical Society of Quebec joined in urging the establishment of a Geological Survey upon the Government, with the result that the modest sum of £1,500 sterling was granted for the purpose of beginning such a survey.

Mr. Logan, afterwards so well known as Sir William Logan, was the first geologist appointed. He entered upon his duties, in 1843, with the greatest possible zeal, and for more than twenty-five years the history of the Survey and that of its director were the same.

The field work of the Geological Survey necessarily began with exploratory trips in which the main features to be dealt with, in a country almost entirely unknown geologically, were ascertained. In many parts, even of the older provinces, such explorations are still requisite, but in most of these provinces it became possible after a time to proceed with the more systematic mapping of definite areas, the map-sheets produced forming parts of a connected whole. When the great western regions were added to the field, these could only be attacked by extended exploratory journeys in which geology and geography went hand in hand. As it is now, the field work of the Survey may be divided under three classes: (1) Reconnaissance surveys; (2) the approximate mapping of large areas on a small scale; (3) finished map-sheets on a larger scale, and forming continuous series. All these three classes of work are in progress concurrently in different districts, while the auxiliary chemical, palæontological, and lithological investigations in the office are kept in touch with the field work, and render it possible to bring this together in a homogeneous form. Were there in existence any complete topographical maps of Canada, approaching in accuracy to those which have been made in older countries, much more geological work could be accomplished with a given amount of money and in a given time, and thus the construction of such maps must be stated yet to be, as it has been from the beginning of the Survey, one of the principal desiderata. There is, however, one other matter which at the present moment must be regarded as even more urgent, and one which might be attained within a short time and at a relatively small cost. This is the construction of a suitable and safe museum building for the preservation and display of the important collection which has grown up as the result of so many years of investigation. This collection is not merely a matter of record, closely connected with all the publications of the Survey, but it is fitted to become also a great educational medium in regard to the mineral resources of the country. With proper accommodation its utility could be vastly increased for all purposes.

[1] Abstract of an address delivered before the Royal Society of Canada, by Dr. G. M. Dawson, C.M.G., F.R.S.

Nothing can be adduced which is more creditable to the system of government in Canada, than the quietly persistent and uninterrupted support accorded to the Geological Survey by every political party; but it remains to provide such a museum building and centre for the work as that referred to, and it may be confidently asserted that nothing would be more favourably received by the general public. This museum should be of a national character, and there is every reason to hope that when it is undertaken, its plan will include provision for all the valuable collections which have been or may be made by the several Government departments, so that it may form in effect a representation of the sources, the history and the various lines of activity of the whole country.

METEOROLOGICAL SERVICE AND MAGNETIC OBSERVATORY.

Although the first scientific branch of the Government service established by Canada, it must be noted that several years previous to its inception the Magnetic Observatory had been founded at Toronto. It was established as the result of representations made by the British Association at its meeting in Newcastle in 1838, acting in conjunction with the Royal Society of England, and as a part of a system of magnetic research on sea and in the colonial possessions of Great Britain. The observations were actually begun in 1839. Meteorological observations had been made concurrently with those relating to magnetism, from the time of the establishment of the observatory; but it was not until 1871 that the Canadian Government first made a grant of 5000 dols. for a meteorological service.

In 1876, the issue of daily weather forecasts and storm warnings was begun, and since that time these have become so much a part of the every-day life of the country, that it is unnecessary to enter into any explanation of their character, or to present any plea in their favour. They are equally important and necessary to the farmer as to the navigator, and are, in addition, of value in a hundred other ways.

There are at the present time over four hundred stations in Canada reporting to the central office, of which twenty-nine make daily telegraphic reports, useful primarily in affording data for the weather forecasts. The meteorological service thus developed naturally from the Magnetic Observatory, and both have become merged in a common organisation, the growth of the meteorological work now perhaps overshadowing the original magnetic purpose of the observatory in its immediate interest, though the importance of the magnetic observations has never been lost sight of.

Respecting magnetic charts of the Dominion, much also remains to be done, for though scattered observations of precision have been made, particularly in the west, no systematic attempt at a magnetic survey has been undertaken since that accomplished in an extended journey through the northern parts of the country in 1842 and 1843, by Sir J. H. Lefroy. It is well to remember that the magnetic pole itself is situated within the limits of Canada, and that problems of the greatest importance, both from a purely scientific and from a practical point of view, call for solution by a systematic study of its secular movement, as well as of any changes in intensity and dip by which this may be accompanied. These are all strictly domestic problems, and they should not be left for solution to enterprise from abroad.

EXPERIMENTAL FARMS.

This branch of the public service was established as the result of the recommendation of a select committee of the House of Commons appointed in 1884 to inquire into the best means of encouraging and developing the agricultural resources of Canada. The "Experimental Farm System Act" was passed in 1886, and the organisation of the work began in the same year.

It is thus only about eight years since the initial steps in this new scientific enterprise of the Government were taken, but in that time, thanks to the energy and ability of the director and staff of the farms, great progress has been made, and the way has been opened in many directions for still further usefulness. Besides the central farm at Ottawa, which was first undertaken, branch farms have been established for the maritime provinces, Manitoba and the north-west territories, and British Columbia.

If any line can be drawn between that which may be described as strictly practical and that which may be called purely scientific work, it will be found to run through the centre of the field of operations of the experimental farms. An inspection of the reports already published will show that the work consists largely of submitting actual observations in the field to scientific tests, and in the application in turn of the best results of scientific knowledge to matters of every-day importance on every farm throughout the land.

The following are among the many lines of work undertaken in this service:—

One is the origination of new crosses or hybrids of cereals, fruits, and other useful plants to meet the requirements of the varied climates and conditions of different parts of Canada.

Other branches of the work involving much original research are: the investigation, by chemical analysis, of soils, in their relation to fertilisers, and of grains, grasses, fodder plants and other products of the farm, by which a fundamental knowledge of their respective value and of the best and most profitable methods of their treatment may be arrived at, and the study of insects and parasitic plants injurious or beneficial to vegetation and to stock, such as to enable the pests of the agriculturist to be combated either by methods which may be classed as direct, or by means which are indirect. The latter implies a study of the life-history of the forms to be dealt with, including not only those which are native to the country, but those also which may be from time to time introduced, such as the Colorado potato beetle, the horn fly, and many others. It includes also the study of the best means of counteracting the attacks by all those lower forms of vegetation, known as rust, smut, mould or mildew, that prey upon the plants which are the special care of the farmer.

Even in connection with the familiar and almost world-old operations of butter and cheese making, the results of purely scientific investigations are now being proved to have a great importance. The best mechanical methods of dealing with the milk from which these are made, are not here referred to, but the fact that the nature of the vegetable ferments which act upon this milk and upon the cheese, after it has been produced, are now known to give character to the product; that is to say, the effect of inoculation of the mass with some particular species of ferments is favourable, while the presence of others is deleterious. Thus the results obtained in the whole field of bacteriology are being made contributory to the success of the dairy. Already in Denmark "pure cultures" of certain kinds of ferments are beginning to be regarded as necessary to the success of the butter-maker, and essays of a similar kind are actually in progress here.

It is not possible to refer in detail to the numerous experiments and tests, completed or in progress, of varieties of plants and animals which may be already well known, but of which it is desirable to ascertain those best suited to the actual circumstances of the country. Nor is it possible to enter into questions such as the tests of fertilisers, the testing of the vitality of seeds, or the propagation of trees suited for planting on the plains of the north-west. Though a part of the useful work of the farms, these do not imply original research in the same measure with those subjects already alluded to. Neither is this the time to dwell upon the methods adopted of making the information gained available to the public, such as the publication of special bulletins and reports of progress, the distribution of samples of seed grain (which in 1892 reached the number of 30.000) and of young trees for plantations.

Before concluding this brief review of the several branches of scientific research or work carried on by the Government, allusion must be made to several comparatively late undertakings of this nature begun under the auspices of the Department of Marine and Fisheries.

Under the name of the "Georgian Bay Survey," a hydrographic survey of the Canadian portion of the Great Lakes was begun in 1883, and several excellent charts of the northern part of Lake Huron have already been published.

When the British Association met in Montreal in 1884, a committee of that body, which had for many years been engaged on tidal determinations, interested itself in the extension of such observations to Canadian waters, and a joint committee of the Association and of the Royal Society of Canada was formed, by which the importance of such observations, made systematically and with modern appliances of accuracy, was urged upon the Government. In 1890 a beginning was made in this work, and provision has since been made for its continuation and extension.

Another promising departure is the initiation of a scientific study of that most important element in the welfare of the country, the fisheries. Much has already been done in Canada in the matter of the propagation of food fishes, but much yet remains to be done in investigating the conditions of the fisheries of both salt and fresh waters, and it may now be anticipated that before many years an important basis of fact will have been built up upon this subject.

One important line of inquiry must yet be mentioned in which no systematic beginning has been made, either under the auspices of the Government or by any society or institution especially devoted to it. This is the field of ethnology, which in Canada is a very extensive one, and which calls for immediate effort, inasmuch as the native races, with which this study is concerned, are either rapidly passing away or are changing from their primitive condition.

Ten years ago, the Council of the British Association was so much impressed with the urgency of investigations of this kind, that it not only appointed a committee to deal with the subject, but has since given each year a substantial grant from its own funds in aid of this work. The Canadian Government for several years supplemented this grant, and eight reports, filled with valuable observations on the western tribes, have so far, as a result of this action, been published in the annual reports of the Association. It has been decided, however, that the functions of the committee, with the grant accorded by the Association, shall cease this year, so that if further progress is to be made, the matter must now be taken up by the Canadian Government. It is earnestly to be desired that the Government may at least contemplate the attachment, either to the Indian Department or to some other department, of a properly qualified ethnologist, by whom these investigations may be continued.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 6, 1894.—"Experimental Researches on Vegetable Assimilation and Respiration. No. I. On a New Method for Investigating the Carbonic Acid Exchanges of Plants." By F. F. Blackman, B.Sc., Demonstrator of Botany in the University of Cambridge.

This paper consists of a description of a complicated apparatus for the estimation of very small amounts of CO_2, which is especially adapted for biological research.

By its aid the evolution of CO_2 by a single germinating seed, or by a small area of a foliage leaf, can be accurately estimated from hour to hour without a break, for any desired time, while for the same area of leaf the more active absorption of CO_2 in assimilation can be easily determined for such short periods of time as fifteen minutes, and that at the same time separately for the two surfaces of one and the same leaf area. Further, for the purposes of this assimilation, air containing any proportion of CO_2, however small, can be supplied continuously to the tissue under investigation. The apparatus is practically in duplicate throughout, and strictly comparative double experiments can be performed.

The experiments are carried out in a continuous current of air at atmospheric pressure; the actual estimation of the CO_2 is accomplished by leading this through baryta solution, of which only a small quantity is used in each case, and the whole of it afterwards titrated *in situ* in the absorption tube, to which only air freed from CO_2 is otherwise admitted.

The following communication illustrates the applicability of this apparatus to the investigation of minute quantities of carbon dioxide:

No. II. "On the Paths of Gaseous Exchange between Aerial Leaves and the Atmosphere."

Conclusions.—(1) That if the amounts of CO_2 evolved in respiration by the two surfaces of any leaf area be determined, it will be found that there is a very close relation between these amounts and the distribution of the stomata. In those leaves with no stomata on the upper surface, practically no CO_2 is exhaled from that surface, and all escapes from the lower surface. When stomata occur equally on the two surfaces the amounts of CO_2 exhaled are equal on the two surfaces, and so on.

(2) Similarly with assimilation, no CO_2 is absorbed by an astomatiferous leaf surface, and when stomata occur on both surfaces, then the amounts absorbed follow the ratios of stomatic distribution.

(3) Boussingault's experiments on the assimilation of leaves with blocked stomata, which have hitherto formed the mainstay of the "cuticular" absorption theory, are completely vitiated by having been performed in super-optimal percentages of CO_2. Their interpretation is exactly the reverse of that usually accepted.

(4) The exhalation of CO_2 in bright light by a leafy shoot in Garreau's well-known experiment, is not the expression of any physiological truth for the leaf, but is only due to the presence of immature parts, or of tissues not sufficiently green, or not fully illuminated. Mature isolated green leaves fully illuminated assimilate the whole of their respiratory CO_2, and allow none to escape from them.

December 13, 1894.—"The Influence of the Force of Gravity on the Circulation." By Prof. Leonard Hill, M.B.

The chief results of the research are contained in the following conclusions:—

(1) That the force of gravity must be regarded as a cardinal factor in dealing with the circulation of the blood.

(2) That the important duty of compensating for the simple hydrostatic effects of gravity in changes of position must be ascribed to the splanchnic vaso-motor mechanism.

(3) That the effects of changing the position afford a most delicate test of the condition of the vaso-motor mechanism.

(4) That the amount of compensation depends largely on individual differences.

(5) That the compensation is far more complete in upright animals such as the monkey, than in rabbits, cats, or dogs, and, therefore, is probably far more complete in man.

(6) That in some normal monkeys over-compensation for the hydrostatic effect occurs.

(7) That in the normal monkey and man gravity exerts but little disturbing influence, owing to the perfection of the compensatory mechanism.

(8) That when the power of compensation is damaged by paralysis of the splanchnic vaso-constrictors, induced by severe operative procedures or by injuries to the spinal cord, by asphyxia, or by some poison such as chloroform or curare, then the influence of gravity becomes of vital importance.

(9) That the feet-down position is of far greater moment than the feet-up position, because when the power of compensation is destroyed the blood drains into the abdominal veins, the heart empties, and the cerebral circulation ceases.

(10) That, generally speaking, the feet-up position occasions no ill consequence.

(11) That the horizontal and feet-up positions at once abolish the syncope induced by the feet-down position by causing the force of gravity to act in the same sense as the heart, and thus the cerebral circulation is renewed.

(12) That firmly bandaging the abdomen has the same effect. While the heart remains normal, and so long as the mechanical pressure is applied to the abdominal veins, the blood pressure cannot possibly fall.

(13) That if the heart is affected, as by chloroform or curare poisoning, the restoration of pressure is incomplete, and it is possible that the heart may be stopped altogether by the inrush of a large quantity of blood, caused by too rapid an application of pressure on the abdomen. More work would be thrown upon the heart than, in its impoverished condition, it could perform.

(14) That vagus inhibition and cardiac acceleration are subsidiary compensatory mechanisms in the feet-up and feet-down positions respectively.

(15) That chloroform rapidly paralyses the compensatory vaso-motor mechanism, and damages the heart.

(16) That ether, on the other hand, only paralyses the compensatory vaso-motor mechanism very slowly and when pushed in enormous amounts.

(17) That the vaso-motor paralysis induced by these anæsthetics lasts for some considerable time after the removal of the anæsthetics.

(18) That chloroform can, by destroying the compensation for gravity, kill the animal, if it be placed with the abdomen on a lower level than the heart.

(19) That elevation or compression of the abdomen immediately compensates for the vaso-motor paralysis produced by chloroform.

(20) That compression or elevation of the abdomen, coupled with artificial respiration and with squeezing of the heart through the thoracic walls, is the best means of restoring an

animal from the condition of chloroform collapse. That these results agree entirely with McWilliams', and are opposed to those of the Hyderabad Commission.

(21) That the feet-down position inhibits respiration, and the feet-up position accelerates it.

(22) That these respiratory results probably depend upon the stimulation of sensory nerve endings by changes of tension brought about by the alterations of position, because the results are abolished by dividing the vagi.

(23) That in the feet-down position the respiration is thoracic in type, and the abdomen is retracted; in the feet-up position the respiration is diaphragmatic and the abdomen freely expanded.

(24) That these types of respiration tend to compensate for the effects of gravity on the circulation, for the retraction of the abdomen in the feet-down position mechanically supports the abdominal veins, whilst the thoracic inspirations aspirate blood into the heart. In the feet-up position the full and free expansion of the abdomen withdraws all obstacles to the compensatory dilatation of the abdominal veins.

In the last part of the paper the medical aspects of this research are discussed. It is suggested that emotional syncope is due to paralysis of the splanchnic area, and a case is quoted where compression of the abdomen immediately removed the syncopal condition. The same treatment, or that of elevation of the abdomen, is suggested for conditions of shock, chloroform collapse, and after severe hæmorrhage.

Finally, a parallel is drawn between some of the results of this research in reference to monkeys and those obtained by Dr. George Oliver on man, by measuring the diameter of the radial artery with his ingenious instrument, the arteriometer.

Physical Society, December 14, 1894.—Prof. W. E. Ayrton and Mr. H. C. Haycraft communicated a paper on a students' simple apparatus for determining the mechanical equivalent of heat. Mr. Haycraft, who read the paper, explained that the object at which the authors had aimed was the construction of an apparatus which could be placed in the hands of junior students, and by means of which a result correct within one per cent. could be obtained, without the introduction of troublesome corrections. The method employed is the electrical one, and the measurements to be made are (1) the value of the constant current passed through the resistance, as given by a direct-reading ammeter; (2) the average value of the P.D. between the terminals of the resistance, as given by a direct-reading voltmeter; (3) the mass of water heated *plus* the water-equivalent of the containing vessel, resistance-coil, and stirrer; (4) the rise of temperature of the water; (5) the time during which the current is passed. Of these the measurements (1) (2) (3) can be effected without the introduction of an error anything like as great as one per cent. The case of (4) and (5) is different. The rise of temperature, to be measured with accuracy, should be fairly considerable, and the same remark applies to the time of heating as measured by an ordinary stop-watch. At the same time, if these two quantities are made unduly great, there will be too great a ratio of heat lost to heat generated during the experiment. The authors consider that, with a given amount of electrical power available, the best conditions will be obtained by making the percentage accuracy of the temperature measurement, the percentage accuracy of the time measurement, and the percentage of generated heat lost by surface cooling equal. Hence they determine the mass of water to be used and the time of heating which may be expected to give the best results. The immersed conductor is a strip of manganin about 0·25 inch wide, 0·03 inch thick, and 5 feet long, which is bent into a series of zig-zags, so as to form a kind of circular gridiron, the successive portions of strip lying all in one plane, and the whole being held rigid by a strip of vulcanised fibre, to which each portion of the strip is screwed. Another precisely similar grid is placed 3 inches below the first, and the two are joined in series, and are mechanically connected together by thin vulcanite pillars. The water is contained in a glass beaker of just sufficient diameter to take the framework of manganin strip. This latter exposes a considerable surface (about 400 sq. cm.) to the water, and is moved bodily up and down during the experiment, thus constituting an efficient stirrer. To allow sufficient freedom of movement, electrical connection is made by means of very flexible leads, each made up of about 210 thin copper wires. The results obtained by students for the heat equivalent of the watt-second have an average deviation from the mean, if several experiments are made, of less than one-half per cent.; and they agree with the best standard determinations within one per cent. Mr. Griffiths thought it inadvisable to provide junior students with apparatus from which every source of error had been eliminated; they were thus led to underrate the difficulty of an experiment, and the care required to obtain reasonable accuracy. Prof. Carey Foster agreed, generally, with Mr. Griffiths, and deprecated the use of direct-reading ammeters and voltmeters in experiments of this kind. He thought it preferable that a student should learn to reduce instrumental readings to absolute measure for himself. Prof. S. P. Thompson dissented from the opinions expressed by the two previous speakers, and thought it was an advantage to students to have the use of direct-reading instruments. Dr. Sumpner described a simple method which he had employed for measuring the mechanical equivalent of heat, and which depended on the heating of a stream of water, as it flowed through a pipe containing the current-conductor. Prof. Rücker was inclined to take an intermediate view of the questions that had been raised. He thought that students should take for granted as little as possible concerning their instruments; but to verify every point, even if practicable, would occupy a great deal of time which might otherwise be more profitably employed. Prof. Ayrton replied, and explained that the calibration of ammeters and voltmeters would be part of the work of a student at another part of his course.—A paper by Prof. Ayrton and Mr. E. A. Medley, entitled "Tests of glow-lamps, and description of the measuring instruments employed," was commenced by Mr. Medley, the latter part of the paper being held over till next meeting. The object of the investigation was to find at what E.M.F. glow-lamps could be most economically run. Too low an E.M.F. gives a low efficiency, and too high an E.M.F. renders the lamps short-lived; so that there must be (for a given lamp) a certain E.M.F. which is more economical to work at than any other. It was also pointed out that, as glow-lamps deteriorate and become less efficient with use, it may be an economy to discard a lamp before the filament actually breaks. The lamp is then said to have reached the "smashing point." Accumulators were used to drive the lamps, automatic apparatus being used to keep the E.M.F. constant, and when a lamp-filament broke, the fact was automatically recorded on a tell-tale.

Geological Society, December 19, 1894.—Dr. Henry Woodward, F.R.S., President, in the chair.—The Lower Greensand above the Atherfield Clay of East Surrey, by Thomas Leighton. This paper embodies the results of the author's examination of the Lower Greensand of East Surrey during the three years 1892–94. The area discussed in the paper extends from Leith Hill in the west to Tilburstow Hill in the east; and the divisions of the Lower Greensand chiefly referred to are those hitherto known as the Bargate, Sandgate, and Hythe beds. The author stated that the Lower Greensand of East Surrey shows that formation to consist of beds deposited in a marine estuary or narrow sea, not far from land and within the influence of strong currents, extending generally from N.W. to S.E., so that, without palæontological evidence, no correlation of beds here with those exposed at Sandgate and at Hythe is possible. He arrived at this conclusion by following the outcrop of the various chert-beds, which, after Dr. G. J. Hinde (*Phil. Trans. Roy. Soc.* vol. clxxvi. 1885), are accepted as of sponge origin (deep-water deposits), and further by following the outcrop of the pebble-beds, described by Mr. C. J. A. Meyer (*Geol. Mag.* for 1866, p. 15).—On the eastern limits of the Yorkshire and Derbyshire or Midland coalfield, by W. S. Gresley. The author attempted to throw light on the question of the easterly extension of the Yorkshire, Derbyshire, and Nottinghamshire coalfield beneath the newer rocks. He noticed the general trend of the strata, the sizes of other British coalfields, the question of the origin of mountains, stratigraphical considerations, and the faults of the North of England.—On some phases of the structure and peculiarities of the iron ores of the Lake Superior region, by W. S. Gresley. The author has studied heaps of ore brought from the region lying south-west of Lake Superior since 1890. He described certain structural features of the ore-fragments, and discussed the evidences of mechanical movements and chemical alteration exhibited by these fragments.

Chemical Society, December 6, 1894.—Dr. Armstrong, President, in the chair.—The relative behaviour of chemically prepared and of atmospheric nitrogen in the liquid state, by James Dewar, F.R.S.—On the use of the globe in the study of crystallography, by J. Y. Buchanan, F.R.S.—A new method of obtaining dihydroxytartaric acid, and the use of this acid as a reagent for sodium, by H. J. H. Fenton.—Essential oil of hops, by Alfred C. Chapman.—Interaction of 1 : 2-diketones with primary amines of the general formula $R'.CH_2.NH_2$ (second notice), by Francis R. Japp, F.R.S., and W. B. Davidson.—The isomeric dinitrodiazoamidobenzenes and their melting-points, by R. Meldola, F.R.S., and F. W. Streatfeild.—On the yellow colouring matter of *Sophora japonica*, by Dr. Edward Schunck, F.R.S.

PARIS.

Academy of Sciences, Dec. 24, 1894.—M. Lœwy in the chair.—On two invariant numbers in the theory of algebraical surfaces, by M. Emile M. Picard.—Displacement of carbon by boron or silicon in fused cast-iron, by M. Henri Moissan. Carbon is displaced by boron or silicon in a fused iron carbide or cast-iron much in the same way that salts will displace each other from aqueous solution. A state of equilibrium is set up between the iron carbide on the one hand, and the iron boride or silicide on the other hand.—On the circulation of the lymph in the small lymphatic vessels, by M. L. Ranvier.—On the importance of hybridisation in connection with the re-establishment of vineyards, by M. A. Millardet.—The Secretary announced the death of P. François Denza, Director of the Vatican Observatory (died December 14).—The elements of the planet 1894 BE, by M. J. Coniel. Provisional elements for the planet BI, by M. Capon. The planet BE is the most favourably situated, among the known planets, for the determination of solar parallax. The planet BI is identical with (369) of the *Annuaire du Bureau des Longitudes*.—Observations of Encke's comet and of the planets BH and BI, made at Algiers Observatory, by MM. Rambaud and Sy.—Observations of Encke's comet, made at Lyons Observatory, by M. G. Le Cadet.—Observations of the sun, made at Lyons Observatory during the third quarter of 1894, by M. J. Guillaume.—On the problem of three bodies. M. F. Siacci calls attention to his paper on this subject dated January 12, 1874. He remarks that a paper of August 27 (*Comptes rendus*, 451), "Sur la transformation des équations canoniques du probléme des trois corps," is a reproduction of his 1874 paper.—Remarks on the matter of a priority claim made by M. O. Staude, by M. P. Staeckel.—On the solution of numerical equations by means of recurring series, by M. R. Perrin.—On a doctrinal point relative to the theory of multiple integrals, by M. Jules Andrade.—On the *abaques* for 16 and 18 variables, by M. A. Lafay.—On the electrostatic capacity of a line traversed by a current, by M. Vaschy. The capacity per unit of length of a cable traversed by a permanent current has the same sense as in electrostatics. With rapidly varying currents, it cannot be supposed that the electric field admits of a potential, hence the notion of a definite capacity disappears.—Electric potentials in a liquid conductor in uniform movement, by M. G. Gouré de Villemontée. At speeds of 33 to 323 mm. per second, the uniform movement of a liquid conductor traversing wide glass tubes of uniform section, does not produce any appreciable difference of potential between two points in the liquid.—Experimental researches on radiation at low temperatures, by M. Raoul Pictet. This is an abstract containing a series of curves showing the variation of radiation with time, and a discussion of these curves.—Contribution to the study of atmospheric ozone, by M. J. Peyron.—On the metallic sulphides, by M. A. Villiers.—Combinations of hexamethylene-amine with silver nitrate, chloride, and carbonate, by M. Delépine.—On the cyano-ethers, by M. Albert Colson.—On the chromates of iron, by M. Charles Lepierre. The author has obtained thirteen chromates, of which two only were known before. Whether prepared from ferrous or ferric salts, all contain ferric iron. All are coloured. They form a series parallel to the basic sulphates of iron.—A new reagent allowing the demonstration of the presence of hydrogen dioxide in green plants, by M. A. Bach. A solution as made containing 0·03 gram of potassium bichromate and five drops of aniline per litre. 5 c.c. of this solution give a violet colouration with two drops of a 5 per cent. solution of oxalic acid only after 36 hours. The colouration is given in the presence of hydroxyl in from 10 to 30 *minutes*. This reagent allows the detection of one part of hydroxyl in 1,400,000. The method of testing green plants is given in detail, and a list of a number of plants showing the reaction is added.—On the valency of glucinum (beryllium) and the formula of glucina, by M. Alph. Combes. β diketones, particularly acetylacetone, form metallic derivatives but yield no acid or basic salts. These derivatives are generally well adapted for determining their molecular weights, and hence the valency of the contained metallic radical. By means of a determination of the vapour density of glucinum acetylacetonate, it is found that glucinum is divalent, and its oxide must be written Be O.—On the constitution of the aromatic sulphones, by MM. L. Zorn and H. Brunel.—On the cephalic lobe of the Euphrosinæ, by M. Émile G. Racovitza.—On the development of the kidney and the general cavity in the Cirripedes, by M. A. Gruvel.—On the functional differences between normal and enervated muscle, by M. N. Wedensky.—On the biological relations between *Cladochytrium viticolum*, A. Prunet, and the vine, by M. A. Prunet.—On a detailed botanical chart of France, by M. Ch. Flahault.—On a peculiar method of dehiscence of the pollen of the fossil Dolerophyllum, by M. B. Renault.

THE ORIGINS OF ART.

Die Anfänge der Kunst. By Dr. E. Grosse. 301 pp. 32 figures in the text, and 3 plates. (Freiburg i.B.: Mohr, 1894.)

DR. E. GROSSE, in his book on "The Origins of Art," has struck out a new and very promising line of research. Other authors may have worked to a limited extent at restricted aspects of the subject, or may have theorised to an unlimited extent; but no one has studied the beginnings and evolution of the arts, with such constant reference to what actually occurs, irrespective of what the arm-chair philosopher imagines might have happened.

Dr. Grosse limits its present investigation not only to primitive art, but also to the sociological aspects of the science of art, not because he does not appreciate the other aspects, but because he wished to deal the more thoroughly with this particular problem. His main object appears to be to show, as he expresses it, that "art does not serve only as a pleasant amusement, but for the fulfilling of the most earnest and highest practice of life."

The book contains the following chapters: The aim of the science of art; the method of the science of art; Primitive folk; Art, Decoration, Ornamentation, Representation (sculpture and painting); Dancing, Poetry, Music, and Conclusion. The method adopted is that of comparative ethnography, and our author confines his attention to the lowest and least settled peoples—to the hunter-folk. In order to eliminate as far as possible the secondary factors of race and climate, he studies the condition of each art among the following peoples: Australians, Mincopies (Andamanese), Bushmen, Eskimo, and Fuegans, with occasional references to other peoples.

Each of these chapters is treated in so fresh and suggestive a manner, that one is tempted to quote largely; but a summary of the general conclusions will give a fair idea of the scope of the book. The chapter on dancing is particularly interesting, and the importance of the dance in social evolution is clearly brought out; no one who has witnessed and studied various kinds of savage dances, can fail to feel that they have a significance and value which is entirely lost in the dances of civilised people. "The pleasure of strong and rhythmical movements, the pleasure of imitation, the pleasure of giving vent to the feelings, these factors," writes Dr. Grosse, "give a complete and sufficient explanation of the passion which primitive folk have for dancing." At the same time, he points out that the occasional assembling for social dances induces co-operation among loosely-connected hunter-folk. "It is perhaps along with war the one factor which causes the members of a primitive group to vividly feel their solidarity, and it is at the same time one of the best preparatives for war. It is difficult to over-estimate the value of primitive dances in the culture-development of mankind."

It is found that the artistic creations of the hunter-folk have by no means arisen from purely æsthetic intentions, but they serve at the same time for some practical object, and frequently this latter appears to be the chief motive. Primitive ornaments are not originally and essentially employed for decoration, but as significant marks and symbols. In other cases the æsthetic intention certainly predominates, but, as a rule, it is only in music that it appears as the sole motive.

Although artistic activity, as such, hardly anywhere occurs at the lowest grades of culture, still it is everywhere recognisable, and essentially of the same character which one finds in the higher grades of culture. Only one art, architecture, is wanting among any of the hunter-folk. Herbert Spencer suggested that the three main groups of poetry—lyric, epic, and dramatic—were evolved in the course of the development of the higher culture from an undifferentiated primitive poetry; but these are already to be found in an independent position of their own at the lowest culture grade.

Primitive art forms are constructed according to the same laws as the highest creations of art, the great æsthetic principles of rhythm, symmetry, opposition, gradation and harmony are employed by the Australians and Eskimo as well as by the Athenians and Florentines. The sensations of primitive art are narrower and coarser, their materials are more scanty, their forms are poorer and more clumsy; but in its essential motives, means, and aims, the art of primitive times is one and the same with the art of all times.

Dr. Grosse does not believe that racial character has a decided determining significance in the development of the art of a people at the lowest grade of culture, but that the individuality of the folk, as well as that of individuals, continuously increases with the course of their development. The uniform character of primitive art is due to a uniform cause, and that culture factor is the uniform character of the condition of life of the hunter-folk, irrespective of race or latitude.

The particular kind of production of a people depends, above all, on the geographical and meteorological conditions under which they live. The hunter-folk have remained hunter-folk—not, indeed, as the older ethnologists believed, because they were from the very beginning condemned to stand still through a faulty disposition, but because the nature of their native country prohibited progress to a higher form of production. Herder and Taine maintain that climate exerts a direct influence on the spirit of a people and the character of their art; but Dr. Grosse claims to have proved that the influence is indirect—the climate commands the art through the production. It is doubtful whether this can also be proved for the art of the higher folk, since people provided with a richer culture have made themselves in their production independent of the influences of climate. The progress of culture emancipates the folk from a slavery to nature to a mastery over nature, and one may dare to assume that this also finds a corresponding expression in the development of art.

There are no peoples without art, and even the lowest and roughest races devote a great part of their time and energy to art; to art, adds Dr. Grosse (perhaps somewhat unjustly), which is looked down upon by civilised nations from the height of their practical and scientific acquirements, and treated mainly as an amusement; but from the standpoint of modern science it is incomprehensible that, if such an immense amount of energy was diverted from the conservation and development of the social organism and devoted to æsthetic creation and enjoyment, Natural Selection would not step in, and long ago have rejected those peoples who wasted their energy in so unproductive a manner, in favour of other and more practically endowed folk. The conclusion is therefore arrived at that, from the very beginning, primitive art, besides its immediate æsthetic significance, must also possess a practical advantage for the hunter-folk.

The primitive arts operate in very different ways on primitive life. Ornament demands technique above everything. Ornament and the dance play an important part in the intercourse of both sexes, and through their influence on sexual selection probably serve for the improvement of the race. On the other hand, some of the arts increase the power of the social group in its resistance to hostile attacks; for example, certain decoration is employed to frighten opponents; poetry, dancing and music stimulate and encourage the warriors. The most important and beneficent effect which art exercises on the life of the folk consists in the consolidation and broadening of the social relationship. Not all arts effect this to an equal degree. While dancing and poetry seem predestined to this through their innate peculiarity, music is, from the same cause, almost quite excluded from it. But the effect of the two former varies according to the stage of culture of the people; for example, dancing loses its influence as soon as the social groups become too large for them to be united in one dance; and, on the other hand, poetry has to thank the printing-press for its incomparable power. Among the hunter-folk, dancing is the most important social influence; for the Greeks, sculpture embodied the social ideal in the most effective form; in the middle ages, architecture united souls and bodies in the halls of their gigantic domes; in the Renaissance, painting employed a language which is understood by all the cultured peoples of Europe; and in recent times, the reconciling voice of poetry rings amid the clash of arms and the conflict of classes and peoples.

As science enriches and elevates our intellectual life, so art enriches and elevates our emotional life. Art and science are the two most powerful means for the education of the human race. No pastime therefore, but an indispensable social function is art, one of the most effective weapons in the struggle for existence, and consequently it must develop itself always more richly and powerfully through the struggle for existence. Art is a social function, and every social function must serve for the conservation and development of the social organism. But it is wrong to demand of art that it should be moral, or, more correctly, moralising, for then one demands that art shall no longer be art. Art serves social interests best when it serves artistic interests.

From the foregoing account it will be seen that this book deals largely with the sociological aspects of æsthetics; and it is not only a study of primitive art in the widest sense of the term, but it is also a study of some of the factors of social evolution. It is certainly a book which should be translated into English, in order that it may obtain a wider circle of readers.

ALFRED C. HADDON.

FORBES'S HANDBOOK OF MONKEYS.

A Handbook to the Primates. (Allen's Naturalists' Library.) By H. O. Forbes. 8vo. 2 vols. illustrated. (London: W. H. Allen and Co., Limited, 1894.)

OF the series of which the present work forms a part, five volumes have now made their appearance, namely, one on Marsupials and Monotremes, one on British Birds, a third on Butterflies, and the two now under consideration; while a sixth, on British Mammals, is now in the press. In the three volumes previously issued, it was found practicable to make use of the original plates (with the addition of a few new ones) from the old "Jardine's Naturalists' Library"; but those in the volume in that series devoted to monkeys were such grotesque caricatures, that both editor and publisher were soon convinced that their reissue was impracticable. Consequently, the plates (twenty-nine in number, in addition to several maps) in Mr. Forbes's volumes have all been prepared from entirely new sketches from the pencil of Mr. Keulemans. Whether the lithographers have been quite as successful with some of these as they might have been, we think is doubtful; the colours in some instances being decidedly too bright, while in others the execution is too coarse, and not sufficiently detailed. As a whole, however, they are very creditable, while some, such as the portrait of the Aye-aye, forming the frontispiece to the first volume, are admirable specimens of artistic work.

In a series of volumes like those under consideration, it can scarcely be expected that their respective authors should undertake a detailed study of the skins and skulls of each species they describe, as if they were writing a museum catalogue. Nevertheless, we believe that Mr. Forbes has done this in a large number of cases, and has consequently been able to make some important identifications. He had a specially difficult task before him, for several reasons. In the first place, there is no British Museum catalogue of Primates since the small one published as far back as 1870 by Dr. Gray, which is now, of course, totally out of date; and, secondly, the collection of monkey-skins and skulls in the National Collection is far from being anything near as complete as is desirable. So that, even if the author went through the whole series in the groups most requiring revision, it is improbable that his conclusions would in all cases be unassailable. It may be added that the British Museum collection of monkey-skins consists largely of menagerie-specimens, without properly authenticated localities, or without specified localities at all; the reason of this being the well-known dislike of English naturalists and collectors to shoot monkeys.

As against these drawbacks, Mr. Forbes had some compensating advantages, notably the recent description, by Dr. Forsyth Major, of several new forms of Lemuroids, both recent and fossil. Consequently, his volumes contain descriptions of several forms which are not to be met with in any other collective work on the subject. Not the least interesting among these is the gigantic extinct Lemuroid (*Megaladapis*) of Madagascar, which it is possible may have been still living when that wonderful island was first visited by Europeans.

Mr. Forbes follows the classification now generally adopted by English zoologists, including the Lemuroids in the Primates, and commencing his description with the latter, from which he ascends to the higher forms. As the volumes only bear the title "Monkeys" on their covers, it will perhaps be a surprise to many of our readers (as it was to ourselves) to find Man included in the second volume. Although we were aware that many zoologists regarded Man merely as a highly-advanced monkey, yet we believe this to be the first occasion in which he has been termed a "monkey" pure and simply. We trust it may be the last.

We do not propose to criticise any of the author's views as to the limits of species or varieties, or enter into any discussion on the thorny path of synonymy and the identification of imperfectly defined species. And we accordingly content ourselves with saying that his descriptions are, for the most part, accurate and well-written, and that these are enlivened, when occasion requires, with interesting notes on the habits of some of the better-known species. We cannot, however, refrain from entering a protest against the "double-barrelled" system of nomenclature (as exemplified in *Tarsius tarsius*) the author sees fit to employ—to our mind the most inelegant and absurd result of a slavish adherence to priority.

An important feature of the work is the inclusion of all the known forms of fossil Primates. It would, however, have been better had the author consulted a text-book of geology, as we should not then have been told that while Lemuroids are met with in the Quercy Phosphorites and the Hordwell beds of Hampshire, yet (vol. i. p. 111) "in strata of *Oligocene*[1] and older Miocene age no Lemuroid remains have come to light in Europe." We have likewise some doubt as to the alleged Ungulate affinities of the Tertiary Lemuroids referred to on the page last cited; and, indeed, it seems to us incredible that an animal whose position is admittedly in the Primates, can at the same time be allied to such widely different groups as the Ungulates and the Insectivores, although this is stated by the author to be the case. One other criticism, and we have done. On p. 217 of the second volume it is stated that to the genus *Simia* "has been referred a molar tooth found in the Pliocene strata of the Sivalik hills in India. It is considered to belong to an Orang-Utan, *Simia satyrus*." We have the best reasons for believing that the specimen in question is a canine tooth, and likewise that the palæontologist who made the generic determination would be surprised to learn that he had identified it with a living species.

An especial feature of Mr. Forbes's work is the attention paid to the geographical distribution of the various species and groups of monkeys and lemurs; this part of the subject being elaborately treated in a series of tables at the end of the second volume, supplemented by eight coloured maps. The details here given will be extremely valuable to all future students of distributional zoology.

The series of which these volumes form a portion, ought certainly to have an extensive patronage from those who are interested in natural history from a popular point of view; while at least some of the volumes—and Mr. Forbes's among the number—will be almost indispensable to professed students of zoology. R. L.

BIRDS OF THE WAVE AND WOODLAND.

Birds of the Wave and Woodland. By Phil Robinson, author of "Noah's Ark," &c. Illustrated by Charles Whymper and others. (London: Isbister and Co., 1894.)

MR. ROBINSON is probably the most popular living representative of a school of writers on natural history, dating its origin from the publication, fifty or sixty years ago, of Mr. Broderip's delightful "Zoological Recreations."

Taking birds and beasts as texts for pleasantly discursive essays, in which field-notes, poetry, and folklore rub shoulders with the latest conclusions arrived at by the learned in laboratories and dissecting-rooms, he and his fellows bridge the gap which separates the writings of such disciples of Gilbert White as the late Richard Jefferies, and "a Son of the Marshes," from purely scientific works.

Anything which Mr. Robinson has to say of the animal creation in fur or feather is sure to be pleasant reading; never more so than when he has at his elbow as adviser on such mysteries as "the miracle of migration" the young lady who wrote the preface to "Noah's Ark." A book with his name on the back, and pictures by Mr. Whymper between the covers, is certain to find purchasers and readers to enjoy it. It is a typical Christmas book, prettily got up, printed on good paper, "leaded" with seasonable generosity, beautifully illustrated, and edited, perhaps rather hurriedly, to be in time for the Christmas market. We notice, for instance, that an excellent sketch of partridges in a stubble field figures in the list of illustrations as "grouse." Again, he tells us (p. 93) that "once upon a time rooks were called crows," and that "as the latter had very evil reputations the former suffered for it." He goes on to give a piece of his mind to "the obstinate people in the world who will not understand that it makes any difference whether they use a right name or a wrong one." On his very next page is a capital picture of a couple of scaly-beaked rooks gossiping by the nest in a rookery at bed-time, with the legend beneath, "*Crows* at Sundown."

The description of the thrush carrying its snails day after day to the same stone for execution, and there "building up in its own way a little shell midden, like those which prehistoric man has left us of oyster-shells and clams to puzzle over," is in his best style. But we cannot help thinking that the cases must be rather exceptional in which the bird, "when driven by stress of weather to the sea-shore, treats the hard-shelled whelks just as it treated the garden snails"?

The pictures seem to us, almost without exception, excellent, and are so important a part of the book that "Birds of the Wave and Woodland," by Charles Whymper and others, illustrated by the pen of Phil Robinson, would have been a scarcely less appropriate title than that which appears on the front page.

The influence of South Kensington is apparent in most of the pictures, and the only serious doubt which suggests itself on putting down a very pleasant book, is whether it might not have been better, somewhere or other, to have acknowledged that many (ten at least) of the best are copies, in some instances almost photographically exact, of cases in the Natural History Museum?

Mr. Robinson has kept his best wine for the last. He has seldom, if ever, written anything more fresh and charming than the description, in his concluding pages, of the voles and water-hens of the osier bed in which in boyish days he dodged his hated enemy the keeper, slipping once, as he tells us, when suddenly surprised, into the water, and sitting there "like a coot with only head above the surface, and that half hidden by reeds!" The boy is father to the man, and we can pay the writer no higher compliment than to say he has proved himself worthy of his parentage. T. D. P.

OUR BOOK SHELF.

Studies on the Ectoparasitic Trematodes of Japan. By Seitaro Goto, *Rigakushi.* (Published by the Imperial University, Tōkyō, Japan, 1894.)

THIS memoir extends to 275 pages, and is illustrated by twenty-seven plates. The species on which these studies were made, were for the most part collected by the author himself, from various parts of the Japanese coast, between the years 1889 and 1892. For the present he omits the Gyrodactylidæ, as his investigations of the anatomy of this group are not yet completed. After a brief introduction, in which the method of preparation is described, the details of the anatomy of the several systems, as met with among the species of the ten genera found in Japan, are given; this is followed by some notes on the habitat, powers of locomotion, food and colouration of the several forms, and then we have the systematic portion. By far the greater number of the species were found attached to the gills of fishes, but several live in their oral cavity, and some even on the outer surface of their bodies. In one remarkable instance, that of *Tristomum biparasiticum*, the worm was found always attached to the carapace of a copepod, itself parasitic on the gills of *Thynnus albacora.* The "looping" movements observed by Haswell have been often witnessed by Goto, sometimes they are performed so rapidly in succession as almost to escape observation; lateral movements in some instances were noticed. Whilst the greater number feed on the mucous slime of their hosts, some were undoubtedly blood-suckers. In the systematic description, attention is drawn to the important specific characters to be found in the "hooks" which are often present, near the posterior end of the body. Thirty species belonging to the following ten genera are fully described: Microcotyle, Axine, Octocotyle, Diclidophora, Hexacotyle, Onchocotyle, Calicotyle, Monocotyle, Epibdella, and Tristomum. While none of the genera are new, some of them have emended diagnoses, and the information about the various species included in each is brought wonderfully up to date. Of the thirty species, all are described as new; one, *Diclidophora smaris*, was found in the mouth cavity of *Smaris vulgaris*, taken in the Bay of Naples; all the rest are from Japan. Owing to the often very imperfect descriptions given by previous describers of species, it is possible that some of those described by Goto may on further investigation rank as synonyms, but most of them are strikingly distinctive forms. *Octocotyle*, Diesing, and *Diclidophora*, Diesing, have been combined by many in the genus *Octobothrium*, F. S. Leuckart; but the author gives good reasons why Diesing's genera should be retained, characterising the former genus anew. The author's drawings have been beautifully lithographed; the plates have been all executed at Japan, and will bear comparison with any similar work done in Europe. A very complete bibliography of the literature cited is appended. We venture to suggest, that it is a duty of all biologists to send copies of their published writings to the Library of the Imperial University of Japan, where they will be used and appreciated.

Woman's Share in Primitive Culture. By O. T. Mason, A.M., Ph.D. Pp. 286. (London and New York: Macmillan and Co., 1895.)

ANTHROPOLOGY—the science of man—has been sadly neglected in the past, but there are signs that it will be more extensively studied in the future. We believe it was a president of the Anthropological Institute who pointed out, a short time ago, that while such societies as the Zoological, Geological, Linnean, and others were in a flourishing condition, the Institute which has for its object the study of man had only a membership of three or four hundred. This strange state of things is difficult to account for, though probably it is due to some extent to the absence of ethnological material to work upon in the British Isles. It is very well known that, in the United States, the Bureau of Ethnology publishes most elaborate reports upon anthropological topics; but the opportunities for such study in America are far greater than they are here. Prof. Mason is one of the foremost workers in the field of ethnology understood in its widest sense, and he is particularly qualified to trace the story of the part played by woman in the culture of the world. The volume in which he does this is the first of an anthropological series intended for the intelligent reader, but instructive enough to satisfy the student. The author describes the work of woman in all the peaceful arts of life, and shows that the past achievements have had much to do with the life history of civilisation. The book is very well illustrated, and is a desirable acquisition to the library of every one interested in woman's work. A large share of attention is given to women of American races; but, as the author is curator of the Department of Ethnology in the U.S. National Museum, this might have been expected.

A Text-book of Sound. By E. Catchpool, B.Sc. Pp. 203. (London: W. B. Clive, 1894.)

AS an elementary text-book dealing with the physical processes which cause the sensation of sound, we think this deserves praise. It will certainly give the student the knowledge required before the more elaborate treatises can be read with profit. The author writes as a well-informed teacher, and that is equivalent to saying that he writes clearly and accurately. There are numerous books on acoustics, but few cover exactly the same ground as this, or are more suitable introductions to a serious study of the subject.

Ottica. By Prof. Eugenio Geleich. Pp. 576. (Milano: Ulrico Hoepli, 1895.)

THIS well-constructed manual will compare favourably with the best elementary text-books of optics. It is attractively designed, handy in size, and scientifically arranged. First the phenomena and theory of refraction, reflection, and dispersion are described; optical instruments form the subject of the second part of the book; interference and dispersion the third part, and optical phenomena of the earth's atmosphere, the fourth part; various interesting notes, and a comprehensive bibliography, conclude the volume. The optics of astronomical instruments are treated much more fully than is usually the case in elementary text-books.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

On the Liquefaction of Gases—A Claim for Priority.

EVER since the year 1883, I have been almost uninterruptedly engaged in the examination of the behaviour of the so-called permanent gases at very low temperatures. During the first few months I performed my experiments together with the late Prof. Wróblewski; afterwards, during a series of years, I was alone; and more lately, I went through several investigations with Prof. Witkowski. The results of my researches I published in the Polish, French, and German languages, whilst they were going on; in the *Reports* of the Cracow Academy, of the Vienna Academy, in *Wiedemann's Annalen*, and in the *Comptes rendus*. My researches are thus well known to the scientific world, and I may add, without boasting, that they have been acknowledged by learned men of different nationalities; they were also known to Prof. Dewar, who repeated them several times, and always confirmed my results—those, for instance, on the absorption spectrum and the bluish colour of liquid oxygen, and on the liquefaction of ozone.

Prof. Dewar at first duly acknowledged those of my experiments which he repeated, but afterwards he changed his behaviour, and in the lectures which he gave in the Royal Institution, and during which he liquefied large quantities of oxygen and air, he never again mentioned that his experiments were merely repetitions of mine, performed and published several years before. This is, perhaps, the reason why the English public, which attended those lectures, grew convinced that the liquefaction of oxygen, and other so-called permanent gases, has been achieved for the first time by Prof. Dewar; and it may be that the Rumford medal awarded by the Royal Society to Prof. Dewar, for the labours which I was the first both to perform and to publish, is due to those very lectures. That my labours should thus have been passed over in silence, is all the more astonishing, because as soon as the description of my apparatus, serving to liquefy large quantities of oxygen and air, was published in 1890, I sent him a reprint of it from the *Bulletin International de l'Académie de Cracovie*. A brief report of the apparatus is also contained in the *Beiblätter* of Wiedemann (vol. xv. p. 29), under the title, "K. Olszewski: Uber das Giessen des flüssigen Sauerstoffs."

There is here no space for me to enumerate all my investigations as regards the liquefaction and solidification of the gases in question; but I intend shortly to publish in the English language a more complete summary of my works, by which the English public will be enabled to see that only a small part of the researches which were performed by Prof. Dewar ought to be attributed to him. For the present, I will only state that all the so-called permanent gases (hydrogen alone excepted) were liquefied in quantity for the first time by me, and that I determined their critical points and boiling points; that nitrogen, carbon monoxide, nitric oxide, and methane were also solidified, and their freezing points determined. By means of solid nitrogen I obtained *the lowest temperature* that ever has been both obtained and measured, viz. $-225°$. Many other gases and liquids were frozen, and their freezing points determined for the first time by me. I must finally remark that I also gave public lectures on the subject in Cracow; the first in 1890, during which I obtained, in the presence of over a hundred students, 100 c.cm. of liquid oxygen; the second in July 1891, during the Congress of Polish Naturalists and Physicians, and then I obtained 200 c.cm. of liquid oxygen in the presence of a good many naturalists, and showed its bluish colour and its absorption spectrum. The only reason that I have never hitherto employed a larger quantity of liquid oxygen or air than 200 c.cm. was the circumstance that this quantity was quite sufficient for my experiments; for my apparatus can be enlarged at will, without changing anything in its construction. I have very often used large quantities of liquid oxygen and air whilst attempting to liquefy hydrogen, and to determine its critical pressure, as well as to inquire into the optical properties of liquid oxygen, as is proved by the whole series of researches, performed together with Prof. Witkowski. CHARLES OLSZEWSKI.

University of Cracow, Austria-Hungary, December, 1894.

I HAVE read the letter of Charles Olszewski, and but for your courtesy in drawing my attention to it would have allowed it to pass without notice. Considering the Royal Society, in the year 1878, awarded the Davy medal to Cailletet and Pictet for their achievements of the liquefaction of the so-called permanent gases, it is hardly likely I could put forward in England any claim for such a result. A reference to the *Proceedings* of the Royal Institution between the years 1878 and 1893 will be sufficient to remove the suggestion that the apparatus I use has been copied from the *Cracovie Bulletin* of 1890. The work of the late Prof. Wróbleski has been fully acknowledged in England, and I am not aware of any injustice done to Charles Olszewski on account of the alleged omission of his subsequent investigations from public notice.

JAMES DEWAR.

The Term "Acquired Characters."

I AM afraid that as Sir Edward Fry has endeavoured to show that the explanation, given by Mr. Galton and accepted by me, of the term "acquired characters" is an absurdity when applied to the consideration of the question as to whether those characters can be transmitted by generation, I must proceed to convict Sir Edward of a loose and unwarranted use of language whilst availing himself of the plausible form of strict logical statements. I am a little disappointed with the value of the results hitherto accruing from the intervention of high judicial authority in a scientific discussion.

Sir Edward Fry asked for a definition of the term "acquired characters." From the observations which accompanied his request, it was evident that he wished for a statement of the meaning attached to the term when it is either asserted or denied that the acquired characters of a parent may be inherited by its offspring.

Mr. Francis Galton gave (and I accepted) as a brief explanation of the term the following: "Characters are said to be acquired when they are regularly found in those individuals only who have been subjected to certain special and abnormal conditions." I took the trouble to expand this explanation of the term at considerable length. Whether Sir Edward Fry has understood what was said, or not, is uncertain. Whether he has, or has not, he proceeds to state that this definition excludes the possibility of the inheritance of acquired characters, and renders the inquiry as to whether characters acquired in one generation may be handed on to the next by inheritance impossible! And therefore, according to Sir Edward, the definition is a worthless one for the present purpose. Sir Edward's argument runs: "Characters can only be found regularly either in individuals exposed to conditions which induce them, or in individuals which have inherited them. If then a character appears *only* in those individuals exposed to certain conditions, it does not appear in individuals by inheritance." That is perfectly correct; but where Sir Edward Fry is entirely wrong, is in his illogical assumption that the words "does not appear by inheritance" are equivalent to "is not transmissible by inheritance"; in fact, that "does not" means "never will or can." Surely when Sir Edward takes pains to use such a technical term as "identical proposition," he should remember the difference between "particular" and "universal." Mr. Galton's definition enables the observer to recognise and select for inquiry an acquired character, viz. one which is found in those individuals only which have been subjected to certain special conditions—that is to say, one which is at a given time and place so found. Nothing is said or implied as to future possibilities. It is the purpose of the inquirer to ascertain whether this acquired character can appear in a later generation as a transmitted character. In the specimens examined it *has not* yet so appeared. As Sir Edward justly observes, since it appears *only* in those individuals exposed to certain conditions, it *does* not appear in individuals by inheritance. But that has nothing to do with the question as to whether it *will* or *can* appear in individuals by inheritance. Accordingly the conclusion reached by Sir Edward Fry, that Mr. Galton's definition of the term "acquired character" reduces the proposition that acquired characters are not transmissible to an identical one, is erroneous, and due to a confusion by Sir Edward of a statement of what is observed at a particular moment with a statement of what must be for all time.

It should be noted that Mr. Galton's words do not furnish, or profess to furnish, a definition by which any character may be assigned to its class as either acquired or inherited. It may well be doubted whether such a definition can be framed in the present state of knowledge. What Mr. Galton's definition or phrase does accomplish, is to point out *some* characters which may certainly be classed as "acquired" and not "inherited," and from the study of which we may accordingly start in the inquiry as to whether or not the acquired characters of one generation may become inherited in a subsequent generation. "Characters," writes Mr. Galton, "are said to be acquired when, &c." This by no means asserts that there are not other characters which should be regarded as acquired, if we knew fully about their history; for instance, at the very moment when our observation is being made on a group of individuals, some might conceivably be exhibiting a character inherited from the last generation, and other specimens might be exhibiting exactly the same character acquired *de novo*. Such cases (supposing that they ever occur) would not help us at all in the attempt to determine whether acquired characters are transmissible; and the fact that they are not included in Mr. Galton's definition (though their existence is not expressly denied) renders that definition a more practical one, and more useful to the experimental naturalist than a more comprehensive definition which could not be brought to a practical issue.

Lastly, it seems to me that Mr. Galton's definition is precisely what Lamarck pointed to in his "Première loi" and the first sentence of his "Deuxième loi." The reciprocally destructive nature of the propositions contained in those two laws I pointed out, in a former letter, and have not yet had the pleasure of seeing, in reply, any defence of Lamarck's position from one of his adherents. E. RAY LANKESTER.

Oxford, January 4.

Boltzmann's Minimum Theorem.

THE remarkable differences of opinion as to what the H-theorem *is*, and how it can be proved, show how necessary is the discussion elicited by my letter on the oversight in Dr. Watson's proof. Each of the four authorities who have replied takes a different view.

Dr. Larmor enforces the view I put forward at the close of my letter, and says that the theorem *is* what I said appeared an *à priori* possibility; and I may here point out that his letter is a complete answer to the argument I used in the *Phil. Mag.* 1890, p. 95, urging that, as there were as many configurations which receded from the permanent state as approached it, there was an *à priori* improbability that a permanent state would ever be reached. This argument was criticised at some length, not really answered, in Messrs. Larmor and Bryan's Report on Thermodynamics (British Association Report, 1891), but the suggestive remarks there given helped me, I think, to arrive (independently) at the complete answer given in Dr. Larmor's recent letter. But my present use of the argument is not that which Dr. Larmor criticises; I now use it as a test of a particular proof of the H-theorem. I say that if that proof does not somewhere or other introduce some assumption about averages, probability, or irreversibility, it cannot be valid.

Mr. Burbury appears to consider that the theorem can only be proved if we assume that some element of the distribution does tend to an average (quite a different position from Dr. Larmor's), and he is as yet unable to state the appropriate assumption except for the case of hard elastic spherical particles colliding or "encountering" (for since a is constant in his last letter, it seems as if the $q_1 \ldots q_{n-3}$ coordinates are really dummies). Yet Mr. Burbury has already given what purports to be a *general* proof of the theorem for any number of degrees of freedom.

Mr. Bryan thinks that a condition which excludes the reversed motion is implied in Dr. Watson's proof, for he says that in taking unaccented letters Ff as proportional to the number of molecules passing from one configuration to another in the reversed motion, I make a less "natural" supposition than Dr. Watson, who takes accented letters $F'f'$. I cannot see what virtue there is in putting accents on or leaving them off, and after a very careful study of Mr. Bryan's letter, I can only think that he has fallen into some confusion owing to the way in which he uses at one time *accented* and at another time *unaccented differentials*, although (as he himself remarks) there is no difference whatever between their accented and unaccented *products*. But even if Mr. Bryan be right, would he put us any "forrarder"? What we want is a *proof* that the collisions will make H decrease, and we can hardly be satisfied with a proof which depends on the previous assumption that the particles do "naturally" tend to move in the desired way.

Dr. Watson meets my reversibility argument by saying that H decreases even in the reversed motion, when the system is confessedly *receding* from its permanent state. No other correspondent agrees with him in this view, which would indeed *take away all physical meaning from the H theorem*, for the decrease of H would then be quite unconnected with the approach to a permanent state. As to the other point, Dr. Watson does not amend his proof himself, but says it is "easy" to do, and so does Mr. Bryan. Yet one has an instinctive distrust of things which are said to be "easily seen," and at all events Dr. Watson's reference to the case in which the theorem is *applied* does not help one in the *proof*, where it is necessary to express *separately* the products of the differentials expressed by the small and capital letters respectively in his "Kinetic Theory."

Mr. Burbury asks why I say the error law has been proved for the case of hard spheres without the use of Boltzmann's Minimum Theorem. I thought Tait had done so (*Trans.* R.S.E. 1886), and at all events I thought the ordinary investigation showed that there was but *one* solution, that of the error law, in that case; but perhaps I am mistaken.

Mr. Bryan says Lorenz gives the clearest account of the assumptions in Boltzmann's theorem. He would earn our gratitude if he would state them in his next letter.

EDW. P. CULVERWELL.

Trinity College, Dublin, December 29, 1894.

Aurora of November 23, 1894.

OBSERVATIONS of this aurora, by Mr. James T. Pope, at Dingwall, in the north of Scotland, have been sent to me by Mr. H. Corder, of Bridgwater, a few particulars having also been recorded here of the appearance, which, although the distance of this place from Dingwall falls but very little short of 400 miles, yet showed some very excellent agreements with Mr. Pope's description.

Beginnings of the aurora were seen by Mr. Pope between 6 and 7 p.m., as a glow which brightened gradually along the eastern, and sent up a few faint streamers from the western parts of the horizon towards the north, until 6.30, gradually fading out, after that, till nearly 7 p.m. The glow then gradually reappeared as a bright band, brighter in the east than in its western half, stretched across the sky from east to west, somewhat southward from the zenith. This band of light continued very bright for some time, but faded out gradually towards 7.30, the streamers in the north-west at the same time increasing continually in brightness.

Near Slough the display was first noticed about 7.15 p.m. as a low ill-defined white bow, stretching, at about half the altitude of those stars above the horizon, from under ζ to under ν Ursæ Majoris (altitudes 19° and 24°, azimuths 13° W. and 16° E.) from north). A little later, towards 7.30 p.m., this arc had become a bright narrow band, a degree or two in width, and about 25° long, extending from η Ursæ Majoris in the west (altitude 15°, 19° W. of north) to a few degrees under γ and β Ursæ Majoris (altitudes 16° and 19°, 2° W. and 6° E. of north) on a slightly downward slope to some degrees eastward from the latter star. It faded out partially about 7.30 p.m., leaving two bright remnants across η, and under β Ursæ Majoris, each about 8° long, while a third just similar wisp of light appeared on the same line's far leftward prolongation; this western offshoot of the band continued with the other two short segments till all had faded out at 7.45 or 7.50, marking the arc's considerable but not otherwise traceable extension westwards, across ϵ, ζ Herculis (altitudes 17° and 15°, 60° and 55° W. from north).

Dingwall is about 390 miles distant from Slough, in the direction 18° or 19° west from north; so that it appears that the strong part of the glow-band seen most brightly in the east from Dingwall, was alone observable here (if we except the light-wisp in Hercules towards the west, at last), in the vapoury sky near the horizon.

Beginning with an average altitude of between 9½° and 12°, or of about 11°, at 7.15, the band in growing stronger reached an altitude, at Slough, of 14° or 15° towards 7.30, during about the space of time when it was most distinct, and seen most strongly in the east at Dingwall extending from east to west somewhat southward from the zenith. If its altitude there was at that time about 60°, and at Slough about 13°

above the south and north horizons, respectively, of those places, making the considerable corrections needed by the earth's curvature in the 6° of latitude between them, the resulting height of the luminous arch appears to have been about ninety-five miles above a place about fifty miles south of Dingwall. But the times of observation and the altitudes used being only roughly assigned, and only somewhat vaguely comparable together, an uncertainty of, it may be several miles, must no doubt attach itself to this determination.

Two very slender and fugitive streamers only were seen at Slough to rise from the horizon-glow before half-past seven. But between about 7.35 and 7.40 p.m. a dense tuft of them, 8° or 10° wide, rose from a low, faint light-band then visible at about half the altitude of the short arch-segment across ζ, η Ursæ Majoris, crossing and enclosing that wisp of light, to about half as high again as the wisp's altitude from the horizon. This pillar of light grew faintly red before disappearing, which it did in three or four minutes after springing up, while the rest of the glow and the wisps (the one in Hercules being the last one to be seen) also faded away entirely between 7.45 and 8 p.m. The distinct light-band and the tuft of reddish streamers were the only conspicuously bright phases seen at Slough in the aurora of November 23, between 7.15 and 7.45 p.m., with the exception of the two very faint and slender streamers which rose suddenly to a great height across Ursa Major at about 7.30 p.m.

The base of the pillar-like projection, resting on the faint lower light-bow, was at about 8°, and its summit when highest at about 24° above a part of the north-western horizon between 8° or 10°, and 18° or 20° west from north. Its western side would thus be just vertically over Dingwall, if the lower arch which formed its base was at the same time in the zenith of the latitude of Dingwall; and this, it seems quite probable was actually the case, from the following description of the closing scene, by Mr. Pope, of the aurora's progress after the main belt of light had broken up and dispersed itself, at about 7.30. He writes: "At 7.30 p.m. the glow had almost disappeared, while the streamers at this hour were most intensely bright, and appeared to radiate from a small and distinct part of the sky situated in R.A. 358°, Decl. 43° north. Previous to 7.30, no streamers had been observed to radiate towards the south, but between this time and 8 p.m. streamers were seen radiating from the aforesaid part in *all* directions. After 8 p.m. the display gradually faded out, and at 8.30 very little trace of it could be seen. The appearance at the apparent radiant point when the display was at its height was most interesting; appearing sometimes as a solid mass of aurora, then suddenly breaking up into fragments, and assuming most curious forms, uniting again, and so on. Not the slightest trace of the display was visible at 10.30 p.m."

The altitudes of 8° and 24° observed at Slough, at the base and top of the dense column of reddish streamers, nearly in the direction (as described above) of Dingwall, must evidently have related as directly and definitely to this fine display of radiation in the north of Scotland, as the foregoing altitudes at Slough of the bright band of light, before 7.30, seemed clearly and obviously to supply good means for determining approximately the band's real height, by comparing them with Mr. Pope's description of his view of the same band at Dingwall.

Making the same needed correction, as before, for the diminution brought about upon the apparent altitudes observed at Slough by the effect of the earth's curvature, we may thus deduce a resulting real height of 75 miles above the earth's surface, approximately, at the bases, and of 193 miles, approximately, above the earth for the summits of the streamers which clustered over the neighbourhood of Dingwall, and produced the magnificent spectacle of the auroral corona in that part of Scotland.

Should notes have been fortunately preserved at any other towns in Scotland at considerable distances from, and especially in lower northern latitudes than Dingwall, of the aspect, times and bearings, or astronomical positions of this short but bright aurora's rather peculiar features of development in its transient display, much better conclusions regarding the real positions and the extent and distribution of the spectacle might, without doubt, be gathered from them, than those above roughly extracted from only very slight descriptions. But the roughly reached results of the heights of the appearance may yet, for the present, not be entirely worthless, on account of the scarcely doubtful identities of the aurora's bright features, which were recorded most dissimilarly in this rather surprising instance, at two so very extraordinarily far separated places.

A. S. HERSCHEL.

Observatory House, Slough, December 24, 1894.

Peculiarities of Psychical Research.

ON page 200 I see that Prof. Karl Pearson suggests that it would be a good exercise for some one with a strictly logical mind and plenty of leisure to criticise "the products of the chief psychical researchers." May I say, as a member of the S.P.R., speaking for myself and fellow-workers, that we ask nothing better than such a studious and searching criticism. One of our main difficulties is that our critics will not take the trouble to study or even read our evidence, but are content to ridicule what they conjecture to be our methods and results from so great an altitude of assured contempt, that we fail to recognise ourselves in their travesty, and are therefore unable to derive much benefit from their utterances.

Thus, for instance, Prof. Karl Pearson, before writing his recent letters, has evidently not taken the trouble to refer even to the abbreviated summary of certain card-drawing experiments contained in Mr. Podmore's little book; otherwise he could hardly make the statements he does concerning the S.P.R. record of them.

He objects to M. Richet's results as giving insufficient odds in favour of telepathy, so that, as he says, it shows want of acumen to adduce them. Would he then regard it as more scientific to suppress them? On the other hand, the enormous odds against chance, shown in Mr. Gurney's trials, he also says, on page 153, show a want of acumen (I don't know why, but I expect because nothing could possibly exhibit anything else on the part of an S.P.R. worker), and that such odds might be otherwise accounted for. Does he then suppose that the odds of, as he reckons them, two thousand million to three are accepted by us as the odds in favour of telepathy? Probably he does, because there is at present no need to be fair to investigators in an unorthodox field; but Mr. Podmore is careful to state the opposite, as follows (footnote to p. 27 of Mr. Podmore's little summary, in the *Contemporary Science Series*, of the evidence for Thought-transference so far as it exists at the present time): "Of course the statement in the text" [viz. that "the probability for some cause other than chance deduced from this result is ·99999998"] "must not be taken as indicating the belief of Mr. Edgeworth, or the writer, or anyone else, that the above figures demonstrate thought-transference as the cause of the results attained. The results may conceivably have been due to some error of observation or of reporting. But the figures are sufficient to prove, what is here claimed for them, that *some* cause must be sought for the results other than chance." And another quotation may be permitted from Mr. Podmore's preface, which ought to silence irresponsible detractors like Mr. H. G. Wells, and others, who seek to lead the world to suppose that we have some cause at heart other than the simple ascertainment of the truth, whatever it is, and that Mr. Podmore, in particular, is a bigoted upholder of the certainty of telepathy. This is the quotation: "The evidence, of which samples are presented in the following pages, is as yet hardly adequate for the establishment of telepathy as a fact in nature, and leaves much to be desired for the elucidation of the laws under which it operates. Any contribution to the problem . . . will be gladly received. . . ."

Now, I observe that Prof. Karl Pearson has a contribution to the problem, for in NATURE of December 27, 1894, p. 200, he refers to certain experiments of his own, wherein by pure chance he obtained results against which the theory of probability also gave large odds. Would he be good enough to let us have these results more precisely, as recorded at the time and signed by witnesses, so that they may furnish us with an example of the methods of a "real scientific investigator"? It will be very unsatisfactory if we have nothing but his memory to rely on for the facts; and as he well knows, it is necessary to have the whole of a large number of trials before deductions from the theory of probability are legitimately applicable.

I observe, finally, that Prof. Pearson, with plenty of good-nature but some lack of originality, has refurbished Dr. Carpenter's old joke about an "ortho-Crookes" and a "pseudo-Crookes," and has directed it against me. I shall be well content if he never manages to find a keener and more effective weapon.

OLIVER J. LODGE.

Liverpool, December 29, 1894.

THE STUDY OF CLOUD.[1]

THIS monograph has been long and anxiously expected by all who take an intelligent interest in the advance of meteorology, and recognise the long and profound study that the Rev. Clement Ley has made of this subject. It is with great regret that we notice that the preface is signed by a member of his family, and that the zealous and energetic watcher of the clouds has not been able to see his own work through the press.

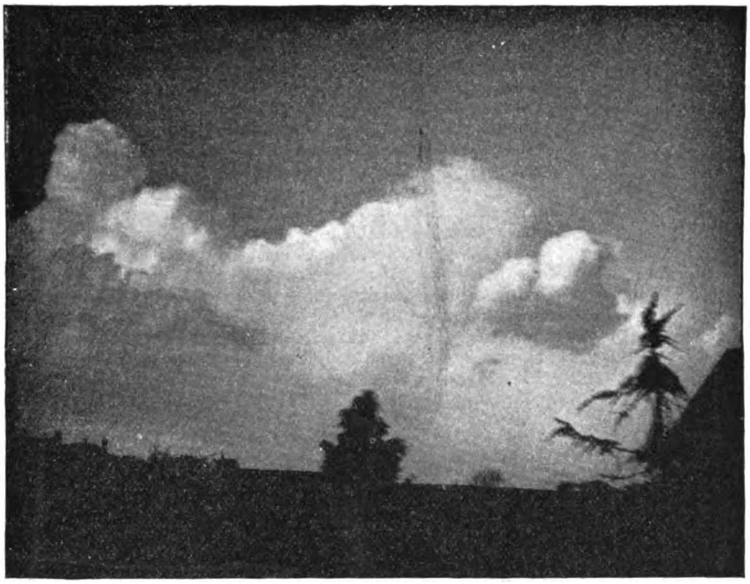

FIG. 1.—Cumulo-nimbus.

We have in this book to do emphatically with Mr. Ley's own observations, his own theories of cloud structure, and his own nomenclature. Although the author acknowledges in the preface the valuable assistance that he has received from the works of other writers, it is curious to notice how seldom in the text these authors are referred to by name. One cannot help feeling that it would have added much to the interest and the instructive character of the book, if Mr. Ley had systematically drawn attention to the work of those who have laboured with scarcely less industry than he has in this department, if he had exhibited the points of difference from, and support given by, other observers, such as Abercromby, Hildebrandsson, Weilbach, and a host of other authorities, who seem sometimes almost ostentatiously ignored. It will be seen that Mr. Ley does not offer anything approaching a history of the subject, either on the theoretical or observational side. Opening with a preliminary chapter on the atmosphere and the movements of vapour-laden air, we have the general principles of cloud formation explained. Although we have been accustomed to think that moisture condensed into cloud can only be driven or rolled about in a limited number of ways, and hence but few really distinct varieties of cloud can be formed, our author subdivides the process of cloud formation under several heads. The process which he terms "interfret" seems very nearly allied to the Luftwogen of Helmholtz, though there is no mention of this authority in the text. Mr. Ley states that when approximately horizontal currents of air differing in velocity and direction move over one another, an intermingling of the particles will result, accompanied by whirls, ripples, and waves, varying in size and shape according to the velocity and direction of the current. This effect he attributes to friction, and this seems to be the chief difference between him and the German physicist, who sees a more complex problem in the mixing of two fluids of different specific gravities. If the colder current is uppermost, the resulting action is called "interfret"; if the warm moist current is above, then "reversed interfret." To clouds formed by the descent of moist particles through warmer and denser air, the term "inclination" is applied, and the final nomenclature adopted rests on subdivisions of these classes of formations.

An adequate nomenclature of clouds has long been, and we think it may be said, is still, a desideratum. Luke Howard's terms still survive, and after nearly a century's use cannot, and will not, be entirely superseded. Stratus, cumulus, and cirrus have too strong a hold on the vocabulary to be dislodged, and however much they may be subdivided, they must remain the basis of classification. Mr. Ley therefore retains these terms, but an eye educated by some fifty years of constant study, has

FIG. 2.—Cumulo-nimbus (same cloud as in Fig. 1).

[1] "Cloudland: a Study on the Structure and Characters of Clouds." By Rev. W. Clement Ley. (London: Stanford, 1894.)

seen and learnt to recognise many varieties of shape and form, arising possibly from real differences of structure, which require distinctive appellations, and make the description somewhat cumbrous. To quote the entire list of subdivisions would occupy no small space. Leaving out of the question fog, which is itself divided into three classes, we have the clouds of interfret, inversion, and inclination, each subdivided into five different varieties. To this list, large as it is, must be added several additional subdivisions, all presenting marks of dissimilarity, and it is suggested, typical of special states of weather in different portions of the globe. Each of these classes is described at considerable length, and many of them are admirably illustrated, both by coloured plates and photographs. We have recently reproduced (NATURE, vol. xlix. p. 342) some admirable specimens of cloud photography, due to S. Manucci of the Vatican Observatory, illustrative of the distinctive characteristics of cloud formation. Mr. Arthur Clayden has secured some very admirable specimens, worthy to be classed with those of the Italian artist. We give in Figs. 1 and 2 the reproduction of the same cloud (cumulo-nimbus) after an interval of ten minutes, in which the shifting character of clouds is well illustrated. The truthfulness to nature is shown very conspicuously in an evening picture of the same variety of cloud (Fig. 3).

But the important question is, will illustrations, however carefully executed, give to persons of ordinary intelligence that insight into cloud structure which enormous experience has given to Mr. Ley, and enable them to discriminate with facility and certainty between the various classes? The author raises the objection, not as existing in his own mind, but as having been suggested to him by others whose opinion he values, that the classification here presented is too complex. We would respectfully associate ourselves with those who have suggested this doubt. Mr. Ley's contention is, that greater simplicity of description might induce a larger number of observers to contribute something, but that the *value* of the whole mass of such observations would be of small amount, through however long a space of time they were continued. The main value consists in the evidence it affords of the different forces at work in the air, and its consequent trustworthiness as a weather guide, and on this point there will be many different opinions. The same description of cloud does not prognosticate the same weather in all countries, or at all times in the same country. The method and cause of development are as important as the character of the cloud itself. Cumulus may sometimes be the promise of a fine day, or prove the precursor of a shower. A man who "forecasts" by the clouds alone, is in the same position as a man who relies on the indications of a wheel barometer. He simply considers one variable in a very complex result. But Mr. Ley looks forward to a time when every man shall be his own "weather prophet," and when every individual and institution may be provided with weather telegrams and the means of correct and intelligent interpretation. In the multitude of counsellors so created there may be wisdom; there will certainly be confusion.

Waiting for this consummation, it seems most desirable that the same kind of cloud should be called by the same name by all observers; and simply having regard to the main divisions, it will be admitted on all hands that this amount of progress has not yet been effected. We have then to consider whether this book, valuable as it is, will promote this end, and we are afraid that it will prove an edged-tool to beginners. To the advanced student it can easily be understood that this work is most welcome, but there still seems necessary a simpler system to serve as an introduction for the tyro. Mr. Ley may very well say that he addresses himself only to skilled observers, and to some this will be a sufficient defence, but this skill is not easily acquired, and we look for a graduated system, along which a student may advance confidently and scientifically. Abercromby and Hildebrandsson recognise and would recommend a classification of ten divisions, a system of which we believe the author disapproves. Captain Wilson Barker would, if we understand his arrangement correctly, still further simplify this system, and therefore it does not seem impossible to lead the student along an easy incline in which he would gradually accumulate experience, rather than plunge him at once into the subtleties and pitfalls which Mr. Ley prepares for the beginner.

FIG. 3.—Cumulo-nimbus (evening).

It is easy to understand how difficult a problem was submitted to the International Meteorological Committee when they were asked to adopt and sanction a uniform nomenclature of clouds, and how prudent they were in declining the invitation (NATURE, vol. xxxviii. p. 491).[1] Simply having regard to the fact, that meteorologists are generally agreed that the same cloud forms and cloud structure are to be met with all over the world, it would seem that an International Congress was admirably adapted for the settlement of such a scheme. But it was felt, and the feeling will be still more general after the perusal of Mr. Ley's book, that our knowledge of the physical and structural process of cloud formation is in a progressive state, and therefore final classification impossible. Mr. Ley would probably be the last to consider that his book possesses the element of finality. He has not only learnt and taught much, but he has also learnt, better than most of us, how much more there is to learn.

W. E. P.

[1] This subject is still engaging the attention of an International Congress (See p. 185.)

SIR CHARLES NEWTON, K.C.B.

THE hand of death has lately fallen heavily on the ranks of the older scholars; and classical archæology has especial losses to record Only a few months back, there passed away Heinrich Brunn, the *doyen* and most picturesque representative of German Hellenism; and we in England have now sustained a loss no less severe. Though Newton had of late years become too infirm for active work, and had in fact done little since his retirement in 1885, it is now, when he has gone from among us, that his loss will be most keenly felt. It was not so much in his actual achievements, though these were considerable enough, that his truest claim upon our recollection lay; nor yet in the fact that he had practically opened up a new science for English scholarship: it was more than all in the personality and force of character of the man, which impressed itself on all with whom he came in contact, and the masterful influence which was by no means confined within the limits of his own science. It was to this that he owed his success; and there have been few instances in which a necessity has been so opportunely met by the man most adapted for it. For when Newton joined the Museum in 1840, the study of actual monuments was still in its infancy; Greece itself was very little known, and a pseudo-classicism had been evolved from the mistaken illustration of literary sources with an often inferior Græco-Roman art. Behind him lay the period of learned and ingenious but useless theory; two things were needed to clear away this tangle of ideas—a fuller supply of the best practical material, and a wider scientific method.

At that time the Departments of Antiquities at the Museum, which now are four, were all united in one. The disadvantages which such an arrangement must have entailed are obvious enough, but there was this compensating advantage, that a young man in Newton's position was at the outset enabled to attain a certain familiarity with the wider aspects of his study, and perhaps a breadth of view and sympathy which is more difficult at present. He was thus by his training, as well as by his natural bent, led to a large view of things.

In an address to the Archæological Institute at Oxford, in 1850, he urges a powerful plea for the comparative method in archæology and, as the necessary corollary, for enlargement of museums. In this address, which as archæological teaching was singularly in advance of its times, the writer has laid down the formulæ upon which the modern science of archæology may be said to take its stand. A museum must not be a mere collection of disjointed, disconnected phenomena, but the central consulting-room, as it were, to which all scientific questions may be referred for comparison and elucidation. Classical art and archæology, like all other studies, cannot but lack perspective in isolation: the external conditions, the ethnographical characteristics, the position of the Hellenic race in its relation to the rest of mankind, their art, architecture, life, and thought must be collated and classified with a due regard to the continuity and correlation of things. The archæologist, in short, "must travel, excavate, collect, arrange, delineate, decipher, transcribe, before he can place his whole subject before his mind. But the plodding drudgery which gathers together his materials must not blunt the critical acuteness required for their classification and interpretation: nor should that habitual suspicion which must ever attend the scrutiny and precede the warranty of archæological evidence give too sceptical a bias to his mind." The key-notes here sounded were kept steadily in mind throughout his whole life. It was but a few years after, that his sojourn in the East, as consul at Mytilene, enabled him to put his ideas into practice, and to initiate for England the "era of the spade."

The discovery with which Newton's name will always be inseparably associated is that of the Mausoleum at Budrum, collections from which now fill almost an entire room at the British Museum. Budrum had been visited by Prof. Donaldson early in the century, and the presentation to the Museum, in 1846, of the twelve slabs removed from the castle of the Knights of St. John, had called renewed attention to this monument. In 1847 Newton published a memoir, in which Donaldson's site was selected as that which probably concealed the ruins—a conjecture which other travellers contemptuously rejected. It was not till 1857 that Newton was enabled to verify his conjecture by actual digging, and the account which he gave of his discovery, in his "Travels and Discoveries in the Levant" (p. 86), is one of the most fascinating episodes in a fascinating book Even when the site was thus determined beyond all doubt, the difficulties had only begun; the obstacles of Turkish officialism and native greed were enough to have broken the heart of a less indomitable energy; but his own untiring efforts, backed by the friendly assistance of Lord Stratford de Redcliffe at Constantinople, brought the undertaking to a well-merited success.

Lord Stratford was only one out of many friends whom Newton succeeded in enlisting in the cause he had at heart; he had pre-eminently the priceless faculty of inspiring others with his own enthusiasm; possessed of considerable social gifts, he was enabled to make many friendships, which served him in good stead both at home and abroad. If a special grant were required, whether for excavating a promising site, or for enriching the Museum with an important collection, he rarely failed to wring a reluctant consent from a Treasury too apt to neglect any cause which is not sufficiently self-assertive. During most of the period of his keepership he was thus able to maintain or to encourage enterprise or exploration abroad, set on foot by men who had caught the infection of his energy in personal contact with himself. Smith and Porcher at Cyrene, Dennis at Benghazi, Pullan at Priene, Salzmann and Biliotti at Budrum and Rhodes, Wood at Ephesus, and, more recently, Ramsay in Asia Minor, all owed the initiation of their enterprise, or very material support, to Newton at home. Perhaps one of his most solid claims to our gratitude lies in the fact that he was thus instrumental in obtaining no less a sum than £100,000 in special grants for the purchase of collections for the British Museum, over and above the annual sums voted by Parliament. Of these the most important was probably the great Blacas collection in 1867, a transaction which is admirably illustrative of Newton's resourceful self-reliance and power. The French Government (and probably others also) were known to be inclined to treat for the collection, and the English representative had at short notice to determine a sum which should be at once enough to carry the position, and yet not be deemed extravagant. Newton telegraphed on the Friday to Panizzi; next day the trustees of the Museum met, Disraeli came purposely to the meeting, and the historic treasure was ours.

To his energetic guidance the Hellenic Society and the British School at Athens both owe in a large degree their initiation and their present position. It was indeed in such practical initiation, and in the inspiration of others rather than in actual teaching, that Newton's true sphere lay. Yet all who know his writings, and still more those who had the privilege of personal intercourse with him, will acknowledge the debt they owe to his teaching, either direct or indirect. To any one regarding the period over which his activity extended, from a time when archæological science was, as it were, casting its skin, down to the complete transformation of to-day, to any one who knows the masses of now useless literature which form the cast-off slough, it is really astonishing to turn to Newton's "Essays on Art and Archæology," and to see how fresh and how living the opinions expressed even more than forty years ago still remain. Though cautious sagacity and a conservative temperament were his prevailing characteristics, yet when the occasion needed he could speak with no uncertain voice; it is a remarkable fact, for instance, that his article on the epoch-making discoveries of Schliemann, written at a time when the attitude of scientific men was still undetermined or opposed, remains to-day, so far as it goes, an admirable exposition of the subject. His attitude on such subjects was specially characteristic of his favourite study—Greek epigraphy—for which a man needs a wide range combined with a patient methodical accuracy. He might, indeed, have said of himself, with his great contemporary, Brunn, "In a critical discussion I would rather err methodically than hit upon the truth without method": a golden watchword for this age of hurry and competition.

NOTES.

PROF. RICHTHOFEN has been elected a Correspondent in the Section de Minéralogie of the Paris Academy of Sciences.

DR. D'ARSONVAL has been appointed to the Chair of Medicine in the Collège de France, in succession to the late Prof. Brown-Séquard.

THE death is announced of Dr. Josef Schröter, Professor of Bacteriology in Breslau University, and distinguished for several important researches in the domain of botany. Among the deaths of other foreign scientific men are: M. Stieltjes, the eminent Professor of Pure Mathematics in the Toulouse University; Dr. C. Studiati, Professor of Physiology in the University of Pisa, and Dr. J. G. Brinton, at Philadelphia. Dr. Brinton was known for his botanical works.

PROF. BLAKE has been appointed by the Government of Baroda to the temporary Directorship of the newly-built State Museum at Baroda, and sails this week for India.

MR. J. E. DUERDEN, Demonstrator of Biology at the Royal College of Science, Dublin, has been elected Curator of the Institute of Jamaica.

THE Paris correspondent of the *Lancet* reports that arrangements have been made at the Pasteur Institute for the immediate despatch of tubes of anti-toxic serum to any part of France. It will thus be seen that M. Roux and his assistants have not been idle. Indeed, both the Institute authorities and the public have worked with a will; the latter having, through the *Figaro*, and by means of gifts made directly to the Institute contributed up to December 31, 1894, no less a sum than 611,000 francs (£24,440). This does not include 100,000 francs (£4000) just voted by the Chambers, and which will doubtless become an annual subsidy. The Institute now possesses, for immunising purposes, a stud of 136 horses, a total that will probably be ultimately increased to the maximum of 150. Of these, twenty are kept by the Municipal Council of Paris at a cost of 20,000 francs (£800) a year, for the benefit of the Paris hospitals and poor. At Villeneuve-d'Étang—a property ceded by the State to M. Pasteur in 1886—there are seventy-nine horses cared for by a capable veterinary surgeon and his staff. That the animals flourish under the *régime* of good feeding and periodical bleedings adopted, is proved by the presence in good health at Alfort of a sturdy Brittany pony which has hitherto supplied no less than 420 litres of blood.

THERE will be a special technical meeting of the Royal Geographical Society, in the Map Room of the Society, on Tuesday, January 22, at 4 p.m., when Prof. A. W. Rücker, F.R.S., will read a paper on "Terrestrial Magnetism."

AN Austrian polar expedition is being organised by Herr Julius von Payer, with the view of securing the artistic representation of the physical features of the east coast of Greenland. The actual work will begin in latitude 74°, and will extend beyond latitude 77°. It is anticipated that the expedition will be ready to start in June 1896.

THE weather has continued very disturbed over the British Islands during the past week; northerly gales have occurred with considerable frequency on our northern and western coasts, but the conditions have been quieter than of late over the southern portion of the kingdom. Heavy snow has fallen in Scotland, causing serious interruptions to the railway and telegraphic services; snow has also fallen in many other parts of the country. Sharp frosts have occurred in the Midland districts, as well as in the north and east; and on Tuesday the thermometer in the screen registered 19° at Wick, while ten degrees of frost occurred in several parts of the United Kingdom.

THE study of the "ejected blocks" from a volcano is a peculiarly interesting one, for by the careful piecing together of evidence much may be learnt of the internal processes which accompany the outward and visible eruptions. This study has been undertaken by Prof. Johnston-Lavis for Monte Somma, and some recently published papers contain a portion of the results at which he has arrived (*Transactions* Edinburgh Geol. Soc. vi. 314). Of the many varieties of stratified rocks that have been torn off from the walls of the volcanic chimney by the rising lava, those of Tertiary age show the least metamorphism; while in the deeper-derived Cretaceous limestones all stages of metamorphism are to be found. The earliest changes appear to be the carbonisation of any organic matter to form graphite, and the recrystallisation of the calcite in larger grains. Then as interchange of constituents takes place between the limestone and the metamorphosing lava, various lime-silicates appear in a fairly definite order, until finally we have formed that great variety of minerals for which Monte Somma has long been famous. The occurrence of *periclase* (MgO) is of interest in view of the abundance of hydrochloric acid among the gases emanating from Vesuvius, for that mineral is artificially prepared by heating magnesia in hydrochloric acid gas. Many of the minerals formed under these conditions of metamorphism tend to decompose rapidly under more normal conditions, and associations of serpentine, tremolite, brucite, &c., are formed, such as are well known in areas of regional metamorphism.

THE analogy between these Vesuvian blocks and certain Archæan rock-masses is carried to a striking extent in a further paper, in the authorship of which Dr. J. W. Gregory joins with Prof. Johnston-Lavis (*Trans. Roy. Dublin Soc.*, vol. v. ser. ii. No. vii.). Here many specimens are described which show in the most complete manner the association of characters that led to the belief in the organic nature of the Canadian *Eozoön*. The authors consequently suggest that the Eozoonal structure in its typical localities was developed in the limestones by the contact metamorphism of the associated crystalline rocks—a view which, they point out, is in harmony with the conclusions arrived at by Prof. Lawson on purely stratigraphical considerations. The disproof of the organic nature of Eozoon may therefore be considered complete.

THE disease of Anbury, or Finger and Toe, is met with wherever the turnip crop is cultivated, but it is probably nowhere more destructive than in the north of England. An experiment bearing on the disease, briefly described in the *Journal* of the Royal Agricultural Society, by Prof. W. Somerville, will therefore interest all agriculturists. The experimenter emphasises the fact that the disease is extremely infectious, and may be easily induced by inoculating a soil perfectly sound with soil from a diseased field. Such diseased soil, however, may be easily disinfected by lime, a fact which points to the pathological phenomena being due to an organism—presumably *Plasmodiophora brassicæ*. This being so, too great care cannot be taken to prevent soil or diseased roots being conveyed from a field which is diseased to another which is sound.

A SOCIETY which has a total of more than eleven thousand governors and members, may fairly be said to be in a flourishing condition. Such is the Royal Agricultural Society; and with so great a membership, it is no wonder that a large amount of important work is carried on under its auspices. The current quarterly *Journal* of the Society has among its contents special articles on the rotation of crops, light railways, and the trials of oil engines at Cambridge. It also contains the annual reports of the consulting chemist, Dr. J. A. Voelcker; the consulting botanist, Mr. W. Carruthers, F.R.S.; and the zoologist, Mr. Cecil Warburton. The report of the Council shows that in the Department of Comparative Pathology and Bacteriology, established at the Royal Veterinary College by the aid of a grant from the Society, the work in the research laboratory has included investigations on tuberculosis, diphtheria, anthrax, and other diseases, and the use of mallein and tuberculin for the detection of glanders and tubercle in the earliest stage. The further experiments which have been made, have materially strengthened the evidence in favour of both agents as aids to diagnosis in doubtful cases of disease. We note that the Council have elected as an honorary member of the Society, Prof. W. Fleischmann, Director of the Agricultural Institute of the Royal University of Königsberg, in recognition of his distinguished services to European agriculture. The annual country meeting of the Society will be held this year at Darlington; Leicester has been chosen as the place of meeting for next year.

EVERY naturalist is acquainted with the elaborate spring-like mechanism by which the woodpeckers and humming-birds are enabled to protrude their tongues with such rapidity for the capture of insect prey. These remarkable instances of adaptation have been more than once described, and some other special modifications of the avian tongue and its bony supports will be recalled by ornithologists. In a recent number of *Der Zoologische Garten* (Frankfurt, xxxv., November, 1894), Herr Schenkling-Prévôt redescribes these cases after a renewed investigation, and also supplies a quantity of interesting information on the form of the tongue and hyoid apparatus of birds in general. The old idea that the woodpecker transfixes its prey with its sharp-tipped tongue is probably not yet extinct, but Herr Prévôt adds his opposition to this opinion, and states that the insects are agglutinated to its tongue by the sticky secretion with which its surface is copiously covered. Although the form of the tongue usually corresponds to the shape of the bill, there are exceptions to this rule, as, for example, in the waders, kingfisher, and hoopoe, which, in spite of their long bills, only possess small cartilaginous tongues; in the pelican, indeed, the tongue is altogether rudimentary. In most birds, whose food consists of seeds, the tongue is dart- or awl-shaped; in others, spatulate; rarely, vermiform or tubular. In some birds, such as the owl, which swallow their prey entire, the tongue is broad and serves as a mere shovel. In the hedge-sparrow, nuthatch, woodcock, and others the tongue is bifid or trifid at its apex, while in the humming-birds the tongue is split into two branches almost to its base, and is used for actually gripping the small insects on which these resplendent little creatures subsist. In a family of parrots (Trichoglossidæ) the tongue is provided at its apex with a brush of some 250–300 hair-like processes. In the parrots, the tongue is thick and fleshy, devoid of horny barbs or papillæ, and is even suspected to possess sense-organs of taste. Herr Prévôt concludes his concise but interesting paper with some remarks on the influence of the form of tongue in birds on their varying powers of articulation. It is interesting to note that the parrots, the form of whose tongues most closely resembles that of man, are able to imitate his language more nearly than any other birds.

THE first number of the *Botanisches Centralblatt* gives, from the annual report of the Société des touristes du Dauphiné, an account of the various attempts to establish Alpine botanic gardens in the Jura, Tirol, Styria, the Bavarian Alps, Switzerland, &c.

THE number of *Bonnier's Revue Générale de Botanique* for December 15, 1894, contains a biographical sketch of the late Prof. Duchartre, with an enumeration of his contributions to physiological, morphological, and systematic botany, amounting to 240 papers or separate publications.

THE first part is published of the *Jahrbücher für wissenschaftliche Botanik* under the new editorship of Prof. Pfeffer and Prof. Strasburger. It contains the following papers:—"Investigations on Bacteria," by Dr. A. Fischer, and "Physiological investigations on the formation of callus in cuttings of woody plants," by Herr H. Tittmann.

LORD LILFORD'S "Coloured Figures of British Birds" have now reached their twenty-ninth number, and contain a series of excellently-drawn chromo-lithographs of our native species. Four or five more parts are required to finish the work, which, when arranged, will fill ten or twelve crown-octavo volumes.

THE veteran naturalist, Dr. R. A. Philippi, of Santiago, has just issued an illustrated memoir, in quarto, on the stags of the Andes, which will form part of the "Annals of the National Museum of Chili." Besides the two ordinarily recognised species of the sub-genus *Furcifer*—*Cervus chilensis* and *C. antisensis*—Dr. Philippi describes a third species, *Cervus brachyceros*, from Northern Peru, which appears to be well established.

THE birds of Bulgaria and the adjacent provinces of Turkey have, hitherto, been little investigated by European ornithologists, and are consequently imperfectly known. A good contribution to our knowledge of this subject has just been made by the publication of Reiser's "Ornis Balkanica." The author is Custos of the Museum at Sarajevo, in Bosnia, and has travelled extensively in the Bulgarian provinces.

THE 119th number of the *Biologia Centrali Americana* of Messrs. Godman and Salvin, which has recently been issued, contains continuations of the "Birds" by Messrs. Salvin and Godman, of the Coleoptera by Dr. D. Sharp and Mr. Champion, of the Hymenoptera by Mr. Cameron, and of the "Butterflies" by Messrs. Godman and Salvin, all illustrated by coloured plates of the highest excellence. Various other subjects are in progress, and there can be no doubt that the work, when complete, will give us an account of the zoology of an important region of the New World, executed in a style and with a completeness which has hardly ever been approached by any similar undertaking.

AN important paper on tropical fodder grasses appears in the *Kew Bulletin* for November. The object of the paper is "to draw attention to a few grasses that have attained to first rank for fodder purposes in the tropics, and to give particulars respecting the conditions under which they have been found to thrive." The information given will be of considerable assistance in indicating grasses suitable for cultivation in tropical countries. It will also show some countries that, while they have been spending time and money in endeavouring to introduce foreign grasses, they have overlooked excellent indigenous grasses close at hand.

MESSRS. BLACKIE AND SON have published a small book entitled "First Stage Mathematics." The contents are limited to the requirements of the Code of the Education Department for mathematics as a specific subject.

THE publication of Mr. Hutchinson's "Archives of Surgery," which has lapsed for six months, is now being resumed. No. 21 will appear in a few days, with additional letterpress as well as nine plates, and this number, which commences vol. vi., will contain a chronology of medicine from the fifteenth to the nineteenth century. The publishers will in future be Messrs. West, Newman, and Co.

A ROUGH list (No. 147) of rare and valuable books for sale, has been issued by Mr. Bernard Quaritch. The list includes a number of important archæological works, and a few works belonging to the natural sciences. Mr. W. F. Clay has also just issued a list of scientific books, including the works on chemistry lately purchased by him from the library of the late Prince Lucien Buonaparte.

WE have received a copy of *El Obrero*, a fortnightly paper published at Quito, Ecuador, with a summary of meteorological observations made at the astronomical observatory at that place for the month of September. Observations in that locality are very desirable, and we are glad to see that their publication is to be continued, and copies to be distributed to a number of places.

THE Meteorological Office of Argentina has just issued vol. ix. of its *Anales* in two large quarto parts, forming a splendid contribution to the climatology of that part of the globe. The first part, which contains 678 pages, gives the observations and the means deduced from them, for Cordova, during the years 1872–1892; while the second part, which extends to 400 pages, contains an exhaustive discussion of the data, and of the influence of the various elements on each other, *e.g.* of wind on temperature, &c. It is not possible to give in a brief space any summary of so comprehensive a work. We merely note that the monthly mean temperature varies between 73° in January and 50° in June. The rainfall varies considerably; the mean of a number of years gives about 26 inches. The Director of the Service is G. G. Davis, who is also a member of the International Meteorological Committee, and attended the meeting at Upsala in August last.

Science Gossip is now one of the brightest and most diversified monthlies for the lover of science. The January number is remarkably good. Mr. J. T. Carrington, one of the editors, contributes a number of replies he has received to a letter asking for an opinion upon the use of the word "scientist." The word is never allowed knowingly to appear in contributions to NATURE. A twin-elliptic pendulum, exhibited by Mr. Joseph Gould at the Royal Society's soirées last year, is described by the inventor, and seven exceedingly fine figures, drawn by means of the apparatus, are reproduced. There is also a summary of Schiaparelli's views about Mars; and a page of astronomical ephemerides and notes, as well as scientific news, and notes on various branches of natural science. We are glad to see that physical science comes in for a fair share of attention, but there is still room for improvement.

SIX volumes have lately been added to the comprehensive series of reprints, "Ostwald's Klassiker der Exakten Wissenschaften," published by Engelmann, of Leipzig. No. 54 contains J. H. Lambert's paper, published in 1772, on the projection of terrestrial and celestial maps. The following number is also on map projection, and is made up of memoirs by Lagrange (1779) and Gauss (1822). Translations of two papers by Sir Charles Blagden, from the *Philosophical Transactions* for 1788, appear in No. 56. The subject is the effect of various substances in lowering the freezing point of water. Treatises on thermometry find a place in No. 57, which includes five of Fahrenheit's papers, three of Réaumur's, and a paper by Celsius. The volume thus comprises all the important communications connected with the foundation of the three thermometric scales. The classical work of Scheele on the nature of air and of fire is reprinted in No. 58 of the series; and No. 59 contains Otto von Guericke's experiments with Magdeburg hemispheres, carried out in 1672. The quaint illustrations of the original paper give this volume additional interest.

THE additions to the Zoological Society's Gardens during the past week include a Black-eared Marmoset (*Hapale penicillata*) from South-east Brazil, presented by the Lord Auckland; a Pardine Genet (*Genetta pardina*), a Two-spotted Paradoxure (*Naudinia binotata*) from West Africa, presented by Lieut. F. E. W. Batt; a Sparrow Hawk (*Accipiter nisus*), British, presented by Mr. A. M. Lees Milne; two Long-nosed Crocodiles (*Crocodilus cataphractes*) from West Africa, presented by Captain F. W. Raisin; a Robben Island Snake (*Coronella phocarum*) from South Africa, presented by Mr. G. R. Picton Thwaites; two Grey Parrots (*Psittacus erithacus*) from West Africa, deposited.

Erratum.—In NATURE of December 13, 1894, p. 157, column two, line one, for "of a" read "near the." The cascade represented in the note serves to show clearly the overhanging ledge of limestone.

OUR ASTRONOMICAL COLUMN.

THE GREATER NEBULA OF ORION.—The numerous photographs that have been taken by means of portrait lenses during the past few years, go to show that many of the so-called celestial spaces are really filled with filmy nebulosities. Dr. Roberts's classical photograph greatly extended the limits of the old Theta nebula in Orion, but few astronomers would care to say that it represents the great "tumultous cloud" in its entirety. Indeed, three photographs obtained by Prof. W. H. Pickering in 1889, with a portrait lens, revealed a large zone of nebulosity surrounding the belt and sword handle, and extending towards γ Orionis. The significance of these photographs has perhaps been somewhat overlooked, but attention is again directed to them by a paper communicated by Prof. E. E. Barnard to *Astronomy and Astro-Physics* for December. By means of a lens only 1½ inches in diameter and 3½ inches focus, Prof. Barnard has recently taken two photographs of the Orion constellation (for the lens takes in nearly the whole constellation at one view), with exposures of two hours and one hour fifteen minutes respectively. These pictures show "an enormous curved nebulosity encircling the belt and the great nebula, and covering a large portion of the body of the giant." Without doubt, the nebulous stream which has left its impression upon Prof. Barnard's photographs, is the same as that of which the existence was recorded by Prof. Pickering. The "Great Nebula" in Orion is therefore but a pigmy compared with the greater nebula thus revealed. It is not too much to believe that in a few years the immense band of nebulosity will be shown to be more or less filled with luminous haze, the old nebula being probably but the brightest part of a nebula involving the whole constellation.

THE TRANSIT OF MERCURY.—We have already noted observations of the transit of Mercury on November 10, 1894, made in Europe and America. News has now reached us of successful observations, made under the direction of Mr. J. P. Thomson, at Mr. F. D. G. Stanley's Observatory, Brisbane. The instrument employed was a 6 inch equatorial by Grubb, stopped down to four inches. Times of contact at egress were carefully taken. When the planet had come sufficiently above the horizon to be observable, it had advanced about two-thirds across the solar surface. The whole periphery of Mercury was remarkably clear and well-defined. There was no trace of haze or vapourous aureola around the disc of the planet, but a bright spot was distinctly seen near the centre. At the instant of internal contact at egress there was a faint phenomenon resembling ligament. This, however, was only momentary. When the external contact occurred, the planet's limb tangential with that of the sun was remarkably clear and sharp. There was not a trace of disturbance, and the phase was regarded as a pure geometrical contact. No trace of the planet's periphery could be seen when it left the solar disc, although it was carefully looked for.

The Government Astronomer at Sydney, Mr. H. C. Russell, states that fifteen photographs were taken of the transit of Mercury. He reports that as the planet crossed the sun it presented the appearance of a round and intensely black disc without any fringe such as has been noticed in former transits, and owing to the unsteady state of the air towards the close of contact, the "black drop" phenomenon took place, preventing clear definition.

AN IMPORTANT ASTEROID.—The minor planet BE 1894 proves to be a very important member of the community to which it belongs. M. Tisserand remarks, in *Comptes rendus* for December 26, that, of all the asteroids, it has the smallest perihelion distance, leaving out of count Brucia (363), of which the elements are very uncertain. When BE is at its descending node, its distance from the orbit of the earth is only 0·67 the radius of this orbit. On account of this circumstance, the asteroid is most favourably situated for the determination of the solar parallax. The elements given by M. Tisserand are as follows:—

1894 November 4·7 Paris Mean Time.

m	...	23° 18′ 38″·5	
π	...	357 25 53·5	Mean Eq. 1894.
Ω	...	212 36 51·4	Mean Eq. 1894.

PROF. ADAMS' COLLECTED MEMOIRS.—A note in the *Observatory* informs us that Prof. R. A. Sampson, formerly Isaac Newton Student at Cambridge, is gradually reducing to order the large quantity of MSS. left by Prof. Adams. The memoirs relating to lunar theory have been completely separated and arranged, and the lectures on Jupiter's satellites are also well advanced. Memoirs on the solution of the infinite determinant, and others on some small matters, have been separated from incidental and preparatory work; but a considerable quantity of matter is still outstanding, so it may be one or two years more before the examination can be completed, and the collected works be ready for publication.

THE BIRD-WINGED BUTTERFLIES OF THE EAST.

IN the days of Curtis and Stephens, the late Mr. W. C. Hewitson was a diligent collector and observer of British insects of all orders, and likewise an ornithologist, who published several editions of a well-known work on British birds' eggs. But the day came when he was to discover, as he says in one of his own publications, that a butterfly might be beautiful, though it was not a British species; and he became thoroughly infatuated with these beautiful things, to the study and illustration of which he devoted the remainder of his life. And this is how it came about, as he used to relate to those who had the privilege of the acquaintance of a kind old enthusiast, whose work was of immense value to the progress of entomology in its day, though he was unable to sympathise with or to appreciate the vast revolution in modern biology which many men with whom he was intimate—and men, too, not much younger than himself, with Darwin, Wallace, and Bates at their head—succeeded in effecting in a comparatively short time.

One day of the days, as it says in the "Thousand and One Nights," he happened to be at Stevens's Auction Rooms, when a lot was put up containing several species of the well-known genus *Adelpha*, Hübner, or *Heterochroa*, Boisduval, as it was then called, which replaces our European White Admirals in South America. The butterflies attracted his attention, for at that time it was a novelty to him to see a number of butterflies so closely resembling each other, and yet quite distinct; and he bought the lot. He turned round, and saw Prof. Westwood, who said to him, "What, are you buying butterflies?" "Yes, I am," he answered; and thus he commenced the formation of his great collection of butterflies, now in the British Museum, which was fed by the cream of the expeditions of Wallace and Bates, and remained unrivalled up to the day of his death, in 1878, though there are now several collections in England, France, and Germany which surpass it.

The exact date when this epoch-making event in the history of the study of butterflies occurred, we do not know. It is true that the first paper published by Hewitson on exotic butterflies related to the genus *Heterochroa*, and was published in the *Annals and Magazine of Natural History* in 1847; but in the previous year, Edward Doubleday had commenced his great work on the "Genera of Diurnal Lepidoptera," the letter-press of which was completed after his death by Westwood; and Hewitson executed all the plates, as joint author. It is, therefore, probable that Hewitson had already commenced the formation of his collection before that time, especially as his own great work on exotic butterflies was commenced before the actual completion of the "Genera."

Yet, since the death of Hewitson, new countries have been opened up, and wonderful butterflies have reached Europe, never dreamed of by Hewitson, or which remained unattainable objects of his desire, to the last. Chief among these may be mentioned the butterflies of Central Asia, a *terra incognita* except for Eversmann's and Nordmann's papers, in Hewitson's time; and the butterflies of the Eastern Archipelago, for the older naturalists, and even Wallace and Lorquin, much as they were able to accomplish, only succeeded in sampling some few islands, and many others now known to produce some of the strangest and grandest butterflies in existence, remained unvisited and unexplored.

Chief among the butterflies of these islands are the grand species to which Boisduval applied the generic name of Ornithoptera, or bird-winged butterflies, of which only a few, and those not the most remarkable, are found on the mainland of India, the Malay Peninsula, and South China. Many of the species are very closely allied, but others are so different that they can hardly be regarded as congeneric; and it will be well to discuss them by groups.

First of all, we may divide them into the black and yellow species, and those with black and green, orange, or blue males; and each of these two main groups includes a variety of species, which are hardly all congeneric.

Two species only, *O. Priamus* and *O. Helena*, were known to Linné. Several more were figured and described before the end of the last century; but only eight species were described as late as 1836, and though several others were afterwards described, Hewitson's collection only included eighteen, counting several forms which he treated as varieties. Now, however, Mr. Rippon's large work, "Icones Ornithopterorum," at present in course of publication, is intended to extend to eighty folio plates. But there is always some difficulty in determining the exact number of species, for these butterflies are variable, and in the numerous islands of the East there are a great number of closely allied local races, and we are hardly in a position at present to determine whether it is best to treat them all as distinct species, or as different forms of two or three, and especially is this the case with the group of *Ornithoptera Priamus*.

It will be best to commence with the black and yellow species, which are found on the Asiatic Continent, and the Malay Islands, and therefore in nearer and more acessible localities than any of the green species, except *O. Brookeana*. They are also found in the Moluccas, &c., but less numerously, being more abundant in the Malay Islands.

Of this group, *Ornithoptera Pompeus*, Cramer, from Java, may be regarded as typical. The males of this and the allied species are of a velvety black, with the nervures more or less bordered with grey, and the spaces between the ends of the veins on the hind margin, bordered with white. The hind wings are of a beautiful golden yellow, intersected with the black veins, and bordered with black along the hind and inner margins. The inner margin forms a fold which conceals the brown scent-bearing scales, and is fringed with long hairs.[1] On the inner margin, the black border projects into the wing in a series of long cones between the nervures. The females are similar, but the grey markings of the fore wings are more extended, and on the hind wings the scent-organs are wanting, and there is a row of black spots opposite the cones of the border, which are often connected into a continuous series, as

[1] See, for a fuller description of the scent-organs in *Ornithoptera*, Haase, "Correspondenzblatt des entomologischen Vereins, *Iris* zu Dresden," I. pp. 93-94.

well as with the cones themselves. The fore wings are long and narrow, measuring about five or six inches from tip to tip, and the hind margin is very oblique. The hind wings are rounded and dentated, but form almost a right angle at the anal angle of the hind wings. Behind the head, we often find a red collar in one or both sexes. We have not thought it necessary to figure a species of this group, representatives of which may be seen in almost every collection of butterflies from India and the adjacent islands; but we have given figures of the larva and pupa of *O. pompeus* (Figs. 1, 2). The transformations of all the species of *Ornithoptera* are very similar, as far as they are at present known; the larvæ are rather short and thick, with rows of long fleshy spines, and with the retractile scent-producing and defensive bifid horn on the head, common to all the true *Papilionidæ*. In the yellow group, these larvæ are generally brown, with a broad pale oblique band about the middle.

The amount of yellow on the hind wings of the butterflies of the *Pompeus* group differs very much. Sometimes we find only a narrow black border, sometimes a very broad one, and sometimes the base is also black, the yellow colouring being restricted to a broad band, or even to a large spot in the centre. Two or three yellow species, found in Malacca, Borneo, &c., of

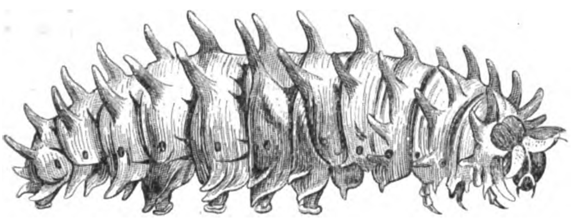

Fig. 1.—Larva of *Ornithoptera Pompeus*, Craw.

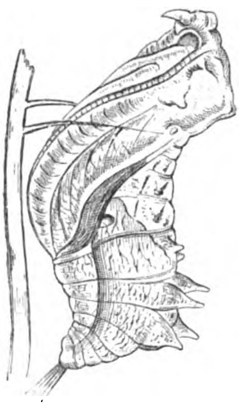

Fig. 2.—Pupa of *Ornithoptera Pompeus*, Craw.

which *O. Amphrysus*, Cramer, is the commonest, are distinguished from the others by having radiating yellow instead of grey lines on the fore wings of the males. Occasionally specimens of the yellow group are met with, with the yellow replaced by deep golden-red; but it is not certainly known whether this peculiarity is accidental or specific.

The grandest of all the yellow species, however, is *O. Magellanus*, Felder, a native of the Philippine Islands. If the butterfly is held towards the light, there is nothing to distinguish it from any other yellow *Ornithoptera*; but if you turn your back to the light, and hold the drawer on a level with your eye, you will see a marvellous iridescence of the most delicate pale silvery blue and green glancing over the whole of the hind wings of the insect. There is nothing to compare with it in any other butterfly, not even in *Morpho Sulkowskyi*; the nearest approach to it is in the iridescence over the red spots in some South American *Papilios* (which, though much smaller, are considered to be closely related to *Ornithoptera*), and in the iridescence over the yellow on the wings of some South American butterflies belonging to the genus *Euselasia*, Hübner. But these latter belong to a different family (*Lemoniidæ*), and are small butterflies, not exceeding an inch and a half in expanse, whereas *O. Magellanus* is a grand black and golden-yellow butterfly, measuring six inches across the fore wings. It is closely allied to several common Indian species, though none of these show more than the very faintest traces of iridescence. But in order to obtain the full effect, it is necessary that *O. Magellanus* should be set *flat*. If the wings are set sloping, according to the old English method, now being rapidly superseded by the flat setting which has always been in use on the continent, the effect of the iridescence is almost entirely lost. *O. Magellanus* is still a scarce insect in collections.

Among the more abnormally coloured species of this group we may mention *O. Plateni*, Staudinger, from the Island of Palawan, in which the male has two broad golden-yellow blotches on the centre of the hind wings, separated by the upper branch of the subcostal nervure; on the underside, and in the female, this colour fills up a large part of the centre of the hind wings. A still more remarkable species was lately discovered by Mr. Doherty in the Island of Salibobo, or Lirung, one of the Talautse Islands, and was described and figured by Mr. Rippon under the name of *O. Dohertyi*. The male is of an intense silky black above, with a slight greenish glow in certain lights; on the underside is a yellow band, parallel to the hind margin, and ceasing before the inner margin. The female has brown fore wings, with the usual grey markings inclining to reddish; the hind wings are darker, with a small irregular buff patch in the centre, divided by the nervures; on the underside this patch is larger, and the ends of the nervures are bordered with the same colour. These butterflies measure about six inches across the wings.

Next to the golden yellow group of *Ornithoptera*, we may place the splendid *O. Hippolytus*, Cramer, the female of which sometimes measures nearly eight inches across the wings.

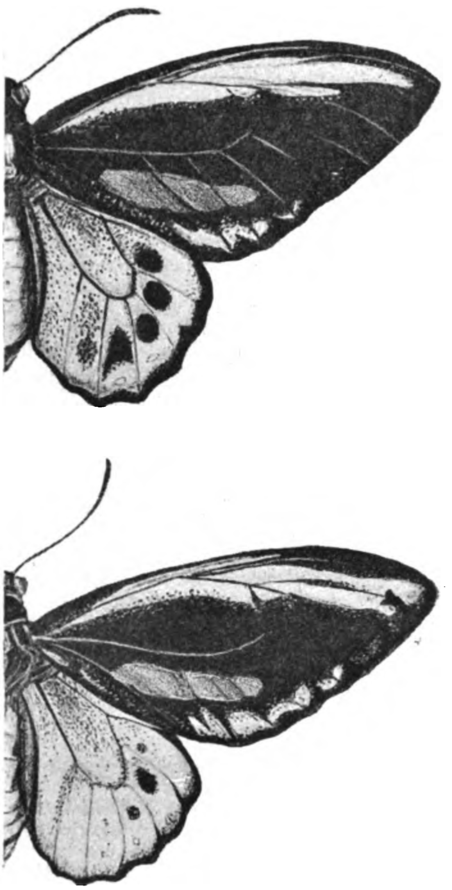
It is not very closely allied to any other species. The fore wings resemble those of the last group, but the hind wings in the male are dark smoky brown, with a row of large yellow spots extending all round the wings, except on the side next the body; these are bordered, both outside and inside, by a row of nearly connected large black spots. In the female the yellow markings are more extended, and the base of the wings is black; the lower part is bluish-grey; and over the yellow and grey part of the wing runs a marginal row of large white spots. The fold on the hind wings is filled with long fluffy white hair. This insect is met with in Amboina, and Piepers, the Dutch entomologist, records his having seen a specimen mobbed and driven away by small butterflies, just as small birds will mob and drive away a hawk in Europe.

Mr. Rippon has proposed the name *Pompeoptera* for the foregoing series of species; but the types of *Ornithoptera* are *Papilio Priamus* and *Helena* of Linné, and as the former is fixed as the type of *Troides*, Hübner, by Hübner's inclusion of it in the second volume of his "Sammlung exotischer Schmetterlinge," *Helena* remains as the true type of the genus *Ornithoptera*, as correctly given by Mr. Moore in his "Lepidoptera of Ceylon," though Dr. Scudder, having overlooked both this point and the impropriety of regarding *Helena* as the type of *Troides*, specifies *Priamus* as the type of *Ornithoptera*, and *Helena* as the type of *Troides*.

Next to the golden-yellow species of *Ornithoptera*, we come to the green, blue, and orange section, to which the name of *Troides* should, as we have just seen, be applied, and of which *Papilio Priamus*, Linné, from Amboina and Ceram, is the type. To *O. Priamus* and its allies Mr. Rippon restricts the name of *Ornithoptera*.

The species of *Troides* are all very similar except in size and colour, and we have copied Mr. Rippon's figures of the smallest species, *T. Richmondia*, from Australia (Figs. 3, 4, ♂; Fig. 5, ♀). This insect varies in size from 4½ to nearly 6 inches in expanse, the female being always the largest; but in most of the other species in the group, the wings expand 6, 7, or even 8 inches in some of the females. The males of this section have velvety black fore wings, with a wide green bar parallel to the costa, and another, more or less extended, at the hinder angle of the wing, running along the inner margin towards the base, and curving upwards along the hind margin. The hind wings are green, with a row of black spots (sometimes reduced to one or two) along the hind margin. There is a long brown patch of raised scales towards the hind margin of the fore wings in the male, which is quite absent in the yellow group (*Ornithoptera*, true). The females are brown butterflies, with two irregular rows of white spots on the fore wings, the innermost very large (though obsolete in some species), and with the hind wings pale beyond the middle, and crossed by a row of black spots; the pale part of the wing is whitish within them, and brownish, or yellow, beyond. The sides of the thorax are generally bright scarlet under the wings, and the abdomen is generally yellow in the males, and brown in the females. These green species are not found in the Malay islands, but throughout all the Moluccan and Papuan islands, as far as Australia; though many of the most remarkable are very restricted in their range, being confined to one or two small islands.

Sometimes, as in the male of *T. arruana*, Felder, a narrow green stripe runs along the median nervure and its branches, in the male. In certain lights the green of the fore wings exhibits very remarkable changes of colour to yellow, coppery-red, or blue; the copper-red is most conspicuous in *T. Pegasus*, Felder, from New Guinea, and the blue in *T. Eumæus*, Rippon, from the Aru Islands.



FIGS. 3, 4.—*Troides Richmondia* (male, two varieties).

T. Eumæus leads us on to *T. Urvillianus*, Guérin-Méneville, from New Ireland, from whence several specimens were obtained during the voyages of the *Coquille* and the *Astrolabe* between 1820 and 1830; but no more were brought to Europe for fifty years. They were named after the famous French Admiral, Dumont d'Urville, a worthy successor of our own Captain Cook; and who subsepuently perished, with his wife and only son, in the great accident on the Versailles Railway, on May 8, 1842, one of the most terrible and fatal of all on record.

In the male of *T. Urvillianus*, all the portions of the wings which are green in other species, are of a deep blue; but with an iridescence or opalescence in various lights, showing green or coppery. *T. Urvillianus* has lately been found in New Guinea, New Ireland, Duke of York Island, and the Solomon Islands. The butterfly does not appear to be difficult to capture, as Mr. Gervase F. Mathew, R.N., frequently found them descend to low bushes; and he also obtained the larva, which is black, with carmine tentacles, and fleshy spines, the latter tipped with black; about the middle of the body is an oblique white stripe. It feeds on a species of Aristolochia, sometimes quite close to the ground.

From *T. Urvillianus*, we may pass on to other remarkable species. One is *T. Crœsus*, Wallace, from the island of Batchian in the Moluccas. Here the green or blue of the species we have already mentioned is replaced by a brilliant golden orange, shading into green in certain lights. Mr. Rippon treats *T. Crœsus* and *Urvillianus* as a separate *section* (*Prismoptera*) of *Ornithoptera* (which name he retains for the *Priamus*-group); but they can hardly be considered sufficiently distinct from the others to rank as a separate *genus*, as he himself admits.

After *T. Crœsus* we may place *T. Lydius*, Felder, which replaces that species in the island of Gilolo or Halmaheira, one of the Northern Moluccas, not far from Batchian. Here the subcostal band on the wings of the male is of a very deep coppery-red; but both in this species and in *T. Crœsus*, the only other mark on the fore wings, except a short dash at the base of the inner margin, is the very large oval brown sexual blotch. The hind wings are of a rather paler colour than the band of the fore wings, and varied with yellow. The female of *T. Crœsus* does not differ much from the ordinary females of the *Priamus*-group, but that of *T. Lydius* is black, with the cell, and two

FIG. 5.—*Troides Richmondia* (female).

complete rows of long spots, concave at the extremity, and the inner row very large, between the nervures beyond the cell. The hind wings are of a yellowish-brown, with the base, nervures, a submarginal row of mostly connected spots, and another on the hind margin, black.

From the genus *Troides*, we pass on to another splendid group, *Ætheoptera* (Rippon), in which the male has apparently no masses of raised scent-producing scales on the wings, and the hind wings are very long. Intermediate between *Troides Crœsus* and *Ætheoptera Victoriæ*, the type of *Ætheoptera*, stands *Æ.* (?) *Tithonus* (De Haan), from New Guinea, a butterfly which remained unique in the Leyden Museum for fifty years. The fore wings of the male, which are seven inches in expanse, are black, with three changing green and yellow bands, two united at the base, the first running narrowly along the subcistal nervure, and much widened before reaching the apex of the wing; the second, broader at the base, extending along the lower part of the cell, and growing broader beyond as it curves towards the hind margin; the third runs along the inner margin, nearly to the hinder angle of the wing. The hind wings are varied with green and golden-yellow, and are narrowly bordered with black. There are three black spots on the hind wings on the upper side, and more beneath, as well as on the hinder part of the fore wings; the abdomen is yellow, with some black spots above on the sides, towards the extremity.

The female is not certainly known, for it is doubtful whether the insect which has been regarded as such may not be that of another species.

Ætheoptera Victoriæ (Gray), the type of its genus, is likewise a species of which little was known for many years. A single female, damaged by shot, was brought back by Macgillivray from the voyage of the *Herald*, and remained unique in the collection of the British Museum for more than thirty years, when several specimens were obtained by Mr. C. M. Woodford in the Solomon Islands. The true *Æ. Victoriæ* proves to come from the island of Guadalcanar, and the male measures six inches across the fore wings, which are long, narrow, and rather pointed. It is black, with a wide green and yellow space for one-third of the distance from the base, and another blotch of the same colour near the costa before the apex, divided by the veins. The hind wings are very concave at the anal angle, and are green, bordered outside by a yellow band, on which stand three orange spots (also visible below, where they have black spots between and beyond them), and beyond this is a narrow

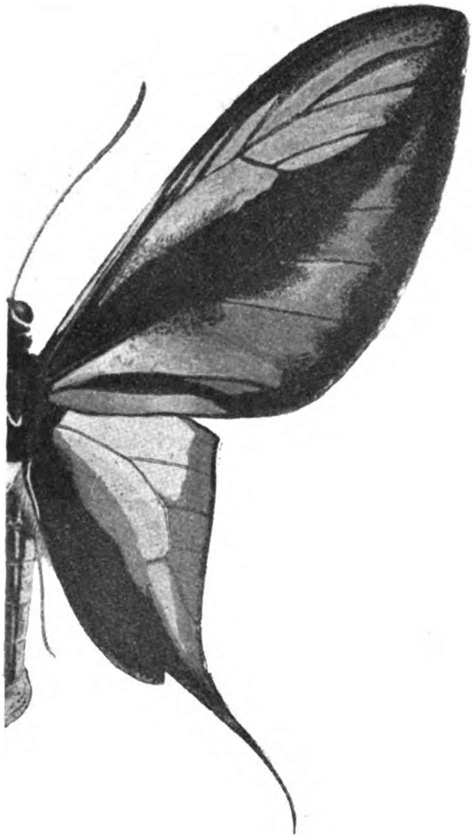


FIG. 6.—*Schoenbergia Paradisea*, Staudinger (male).

black border. The female is a black butterfly, with much broader wings, seven inches in expanse. There is a row of large white spots, and another of submarginal spots on all the wings; on the fore wings a yellow band, white at the extremity, runs along the cell, and another along the inner margin; on the costa of the hind wings is a yellow band. The larva is dark brown, with long carmine fleshy spines; the retractile fork is yellow.

In the island of Malayta is found the closely-allied *O. Reginæ*, Salvin, a larger insect, the male of which has more black on the hind wings, and three orange spots surrounded with green on the orange part of the wing, instead of the yellow band.

These butterflies, as well as *Troides Urvillianus*, frequent the sweet-smelling white flowers of *Cerbera Odollam*, a plant allied to the Oleander, which is common throughout the East Indies and Polynesia.

The next genus, *Schoenbergia*, Pagenstecher, is in some respects the most remarkable of all, as it is the only one allied to *Ornithoptera* which is tailed. The only species, *S. Paradisea*, Staudinger, was captured by natives in the Finisterre Mountains in New Guinea, at a height of 500 metres. The male (Fig. 6) measures five inches across the fore wings, which are black, with two broad green bands glossed with golden yellow, one below the costa, and the other between the cell and the submedian nervure, and curved upwards, opposite the hinder angle of the wing, to beyond the middle of the hind margin. The hind wings are remarkably short, not more than three-fifths of the length of the inner margin of the fore wings, but they are very long and narrow, with the hind margin almost straight, and a tail quite as long as the wing is broad, at the outer angle; the inner margin is lobate. The hind wings are green, more suffused with orange-yellow than the fore wings, and narrowly bordered outside with black, but with the base and inner margin very broadly black.

The females are larger, and exhibit nothing unusual in form or colouring, being black, with two more or less developed rows of white spots on the fore wings, large towards the costa, and diminishing towards the hinder angle, where they converge; on the hind wings is a pale submarginal band, extending over the lower half of the wing, but much narrowed towards the costa; the outer part is yellow, shading within to bluish-grey and whitish; across it runs a row of black spots.

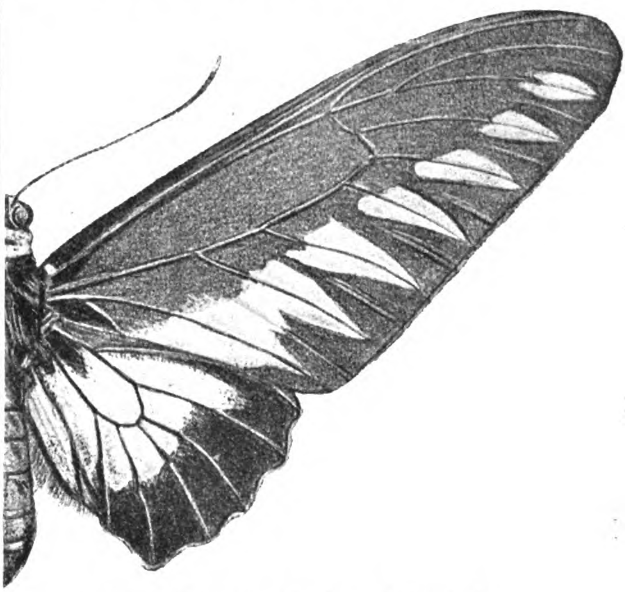

FIG. 7.—*Trogonoptera Brookeana*, Wallace (male).

This is the only known species of the group with tails on the hind wings; but this seems to be a tendency in some Papuan *Lepidoptera*. Thus the true Atlas Moths belonging to the East Indian and South American genus *Attacus*, Linné, are all tailless; but there is a closely-allied genus (*Coscinocera*, Butler) found in New Ireland and at Cape York, which has very long tails; in fact, these moths are probably the largest tailed *Lepidoptera* known.

We have one more Eastern genus to mention, which we have left till last because it occupies a rather isolated position, and would have interrupted the sequence of our genera. This is *Trogonoptera*, Rippon, the type of which is *T. Brookeana*, Wallace, which was discovered in Sarawak, Borneo, by Dr. A. R. Wallace, and named after Rajah Brooke (Fig. 7). It is the only green *Ornithoptera* which inhabits the mainland of Asia (the Malay Peninsula) and the adjacent islands of Sumatra and Borneo. It measures from six to eight inches across the wings, which are black, the fore wings very long, with the hind margin very oblique, and the hind wings short, rounded, and dentated. The front of the thorax and the sides below the wings are crimson. The fore wings have a row of large green submarginal triangles, with the pointed ends resting on the hind margin, and each triangle intersected by a nervure; on the hind wings the whole centre is green. In the female, the green is much more glossed with brassy, and is bordered within with blue, which is rarely the case in the male, and the green markings. which disappear towards the costa in the male, are there in the female replaced by long bifid grey streaks between the nervures. An interesting account of the habits of this species, as noticed by various observers, is given by Mr. Rippon in his "Icones Orthopterorum."

One other species of this genus is known: *T. Trojana*, Staudinger, from Palawan, an island about a hundred miles from the north coast of Borneo. Here the brassy-green spots of the fore wings of the male are shorter and more subconical, instead of forming long isosceles triangles, and there is only a row of connected green spots across the hind wings, bordered within with blue; the base of the wings is also marked with rich blue across the nervures, and along the edge of the fold of the hind wings.
